OFFICERS

President

MILTON FRIEDMAN, University of Chicago

President-elect

KENNETH E. BOULDING, University of Michigan

Vice-Presidents

WILLIAM J. BAUMOL, Princeton University

ROBERT TRIFFIN, Yale University

Secretary-Treasurer and Editor of Proceedings

HAROLD F. WILLIAMSON, Northwestern University

Managing Editor of the American Economic Review

JOHN G. GURLEY, Stanford University

Managing Editor of the Journal of Economic Abstracts

ARTHUR SMITHIES, Harvard University

EXECUTIVE COMMITTEE

Elected Members of the Executive Committee

MOSES ABRAMOVITZ, Stanford University

NEIL H. JACOBY, University of California, Los Angeles

JAMES M. BUCHANAN, University of Virginia

LAWRENCE R. KLEIN, University of Pennsylvania

KENNETH J. ARROW, Stanford University

FRANCO MODIGLIANI, Massachusetts Institute of Technology

Ex Officio Members

JOSEPH J. SPENGLER, Duke University

Fritz MACHLUP, Princeton University

Publication and business office at Curtis Reed Plaza, Menasha, Wisconsin.

THE AMERICAN ECONOMIC REVIEW, including four quarterly numbers, the *Proceedings* of the annual meetings, the *Directory* and Supplements, is published by the American Economic Association and is sent to all members five times a year, in March, May, June, September and December.

Membership dues of the Association are \$10.00 a year, \$8.00 of each year's dues being in payment of a year's subscription both to the *Review* and the *Journal of Economic Abstracts*. Subscriptions by nonmembers are \$10.00 a year. Single copies of the *Review*, \$2.00; of the *Journal*, \$1.00.

Correspondence relating to the *Papers and Proceedings*, the *Directory*, advertising, permission to quote, business matters, subscriptions, membership and changes of address may be sent to the secretary, Harold F. Williamson, 629 Noyes Street, Evanston, Illinois 60201. To be effective, notice of change of address must reach the secretary by the 1st of the month previous to the month of publication.

Second-class postage paid at Menasha, Wisconsin. Printed in U.S.A.

THEORIES OF THE FIRM: MARGINALIST, BEHAVIORAL, MANAGERIAL*

By FRITZ MACHLUP

Last year, when it was my task to plan the program for the annual meeting of our association, a friend suggested that, with twenty years having passed since the outbreak of the "marginalism controversy," it was appropriate to review what has since happened to the embattled theory of the firm. The topic did not fit the general theme I had chosen for the 1965 meeting, but I reasoned that 1966 would give me a good opportunity to undertake the review myself.

The Battlefield Revisited

So let us recall that literary feud and the warriors, and let us revisit the battlefield. The major battlefield was the *American Economic Review*, with six articles and communications between March 1946 and March 1947 [16] [43] [21] [17] [22] [44]. There had been earlier gunfire elsewhere, chiefly in the *Oxford Economic Papers* in 1939 [14]. But, since the shooting then was not returned and it takes at least two opponents to join battle, it must be agreed that the real hostilities were the exchanges in the *AER*.

The fight was spirited, even fierce. Thousands of students of economics, voluntary or involuntary readers, have been either shocked or entertained by the violence of some of the blows exchanged and may have thought that the opponents must have become mortal enemies forever. These readers would have been wrong. Even before we came out for the last round of the fight, we exchanged friendly letters (December 1946) assuring each other that we would bear no grudges.

We have remained the best of friends; for several years now Richard Lester and I have been colleagues in the same department; and, as a token of our friendship, he has generously accepted my invitation to share this platform with me today as chairman of the session. Thus the veterans of both sides of the War of 1946 are now joined in revisiting

* Presidential address delivered, in a shorter version, at the Seventy-ninth Annual Meeting of the American Economic Association, San Francisco, December 28, 1966.

the battlefield. This, incidentally, does not mean that either of us has succeeded in converting the other to the "true faith."

What was the outcome of the controversy? Who won? We could not possibly say if we have not first agreed on precisely what the shooting was about. I have heard it said that Machlup won the battle but Lester won the war. What this means, however, cannot be known unless we know what the issues and objectives of the war had been. Was it merely to make economics safe for or from marginalism? Were there not several other issues being fought over?

Some of the Major Issues

There were no doubt a good many contentions of all sorts—major, minor, essential, incidental, interpretative, factual, methodological, substantive, and all the rest. To present a complete catalogue of the issues involved would be too ambitious a task for this occasion, but a partial listing might be helpful.

The chief issue, of course, was whether marginal analysis was invalid and ought to be discarded, especially as far as the theory of prices, cost, wages, and employment in manufacturing industry is concerned. This issue, however, implied the question of the correct interpretation of marginal analysis, including the tenets of the marginal-productivity principle. In this connection, differences in the models of the firm customarily used in different kinds of analysis became relevant. Involved here was the question of whether the postulate of maximizing money profits led to conclusions very different from those derivable from assumptions of conduct guided by a variety of largely nonpecuniary considerations.

Underlying all these questions were some issues of general scientific methodology: the legitimacy and usefulness of abstract theorizing on the basis of unrealistic assumptions, or perhaps on the basis of assumptions regarded as "reasonable" thought not "universally true." These issues, in particular, were whether an assumption of profit maximization as the effective objective of the firm in the theoretical model may be accepted as a tenable hypothesis only if it can be verified that all or a majority of those who actually run business firms in the real world agree that this is their only or major objective, that they are capable of obtaining all the information and of performing all the calculations needed for the realization of that objective, and are really carrying out the actions found to be optimal in this fashion; or, alternatively, whether all these tests may be dispensed with and the assumption of profit maximization nevertheless accepted as a fruitful postulate from which conclusions can be derived which correspond with what can be observed in the records of prices and quantities.

Concerning the empirical testing of theoretical conclusions, there were issues of the validity of surveys through mailed questionnaires and of the proper interpretation of responses to various types of questions about managerial judgment. In the background of the whole controversy, but undoubtedly of pervasive significance, was the comparative acceptability of empirical findings to the effect that the elasticity of demand for labor was virtually zero and of the conventional theoretical inference that the elasticity was normally above zero.

Realizing how manifold were the issues of the controversy, one can appreciate that no clear decision can be made about its outcome. Some of the issues had been raised decades or centuries before 1946 and were not decided in this confrontation one way or the other. Attacks on the assumption of maximizing behavior and on the lack of realism in price theory have occurred with great regularity ever since "economic man" and similar postulates were introduced. The running battles between the classical and the historical schools were largely on these points. The *Methodenstreit* of 1883-84 dealt essentially with the same issues. And in the United States, institutionalism may be seen as a movement animated by the same spirit of protest against abstract theory.

However, the particular form of explicit marginalism (under the name of "theory of the firm") which became the target of the attacks of 1939 and 1946 had only come into being in the 1930's—if one suppresses the memory of the great master of 1838 [9]. Ironically, some interpreter of recent history of economic thought—I have forgotten who it was—regarded the 1933-34 versions of the theory of the firm [8] [32] [41] as the theorists' concession to institutionalism, as attempts to supplement the neoclassical model of the firm under atomistic competition with some "more realistic" models allowing for a greater variety of conditions. It was this theory of the profit-maximizing firm in all sorts of market positions, in monopolistic and oligopolistic competition as well as in pure and perfect competition, that was attacked by the researchers in Oxford; and it was the marginal-productivity principle in the explanation of the demand for labor on the part of the individual firm that was the prime target of the attack of 1946.

If the chief aim of the attack was to force the abandonment or subversion of marginalism, and if the chief aim of the defense was to turn back the subversive forces and secure the reign of marginalism once and for all, then, to be sure, the war of 1946 ended in a draw. Look at the textbooks and you will find that marginalism has continued to dominate the teaching of microeconomics, perhaps though with occasional reservations and references to current attempts at greater real-

ism. But look at the journals and monographs and you find that research on alternative approaches to the theory of the firm is regularly reported with the implication that a superior theory may eventually replace marginalism. This replacement, however, according to the proponents of the best-known alternatives to marginalism, is expected chiefly with regard to industries where firms are few and competition is ineffective. The marginalist solution of price determination under conditions of heavy competition is not seriously contested.

In pointing this out, I am not trying to claim that marginal analysis is invincible and forever irreplaceable. If I follow the philosophy of science which, instead of pronouncing theories "false" or "true," distinguishes only between those "rejected" and those "still open to criticism" [30, pp. 246-48], the only victory that can be claimed for the cause of marginalism is that it is still open to criticism. I must go beyond this and concede that some anti-marginalist suggestions have led in recent years to a number of revisions in the marginal analysis of the firm which amount to the incorporation of other goals besides money profits into expanded marginalist objective functions.

The Alternative Approaches

In their arguments against the profit-maximization model the various alternative approaches to the theory of the firm are very much alike; only their positive programs can distinguish them.

The program of behaviorism is to reject preconceptions and assumptions and to rely only on observation of overt behavior. Thus, behaviorism rejects the assumption of marginal analysis that economic action is directed by the objective to maximize the attainment of ends with given means, and that business action can be deduced from a postulate that firms attempt to maximize money profits. Instead, we are directed to *observe* how businessmen really act and by what processes they reach decisions.

Perhaps it is not entirely fair to suggest here an association between "behaviorism" and the working program of the proponents of a "behavioral theory of the firm" [10]. In any case, behavioral research proposes to observe and study the "real processes," in the sense of a "well-defined sequence of behaviors" by which decisions are reached in "actual business organizations." The hope—faithfully inductive—is to develop a theory "with generality beyond the specific firms studied" [10, p. 2]. Such a theory will be based on "four major sub-theories" regarding "organizational goals, organizational expectations, organizational choice, and organizational control" [10, p. 21]. It is assumed that five organizational goals—a production goal, an inventory goal, a sales goal, a market-share goal, and the profit goal—become the sub-

ject of bargaining among the various members of the "coalition" which make up the business organization but that the goals are continually adapted and are being pressed with varying force [10, pp. 40-43]. The behavior theory of the firm, with regard to the determination of prices and outputs, will run in terms of a "quasi resolution of conflict" within the organization, of an "adaptively rational, multiple-objective process" with responses to "short-run feedback on performance" and with continuing "organizational learning" [10, pp. 269-70].

This behavioral approach has been characterized as striving for "realism in process," in contrast to approaches aiming at more "realism in motivation" [48, p. 11]. Such realism in motivation is felt to be needed chiefly because of the separation of ownership and control in the modern corporation, whose managements have great power and wide discretion.

In principle, I could expect three different views to be taken regarding the relative independence of corporation management: (1) Whereas owners would run their business chiefly with a view to a maximum of money profits, managers run it with several supplementary and partly competing goals in mind. (2) Whereas owners, especially wealthy ones, would often allow nonprofit considerations to enter their decision-making, managers have a sense of dedication and identification with the business that makes them the more single-minded seekers of profits. (3) Even if managers are inclined to indulge in seeking other goals as long as profits look satisfactory, they are as professionals, trained in the art and science of management, able to make better profits than the owners could ever hope to make running their own show.

What consequences can be drawn from this? One attitude would be to stick with the assumption of profit maximization because it is the simplest and is applicable with much less detailed information to the largest field.¹ Another attitude would be to insist on starkest realism with a complete catalogue of goals and indices of their effectiveness in each firm. A third attitude would be to select two or three of the most

¹ "To use marginalism in the theory of the firm it is not necessary to assert that firms attempt to maximize money profits only nor to deny that a goodly portion of all business behavior may be nonrational, thoughtless, blindly repetitive, deliberately traditional, or motivated by extra-economic objectives. It merely presupposes that the 'rational-economic' portion of business conduct is by and large sufficiently important to affect what is going on in the world to an extent large enough to warrant analysis; and that the substitution of money profits for a composite of pecuniary and nonpecuniary rewards simplifies the analysis so much that the gain in expediency far exceeds the loss in applicability" [23 pp. 30-31]. A similar view is expressed by Scitovsky: "Empirical studies of businessmen's behavior suggest the need for modifying or qualifying the assumption of profit maximization here and there, rather than scrapping it altogether. Accordingly, . . . we shall retain the assumption that the firm aims at maximizing its profit. But we shall regard this assumption as a working hypothesis rather than as a universal rule" [37, p. 111].

important managerial objectives of a type that can be reduced to quantitative analysis and to combine them in a single manageable "objective function." This third approach merges marginalism with managerialism in that it integrates money profits with other managerial goals within one formula of "maximizing behavior."

The question is whether managerial marginalism is prescribed for general application or only for so-called noncompetitive cases. Its most prominent proponents prefer to use the old formula, based on profit maximization, in situations where competition is effective and managerial discretion therefore narrowly circumscribed. In the next sections we shall discuss matters that at first blush may seem unrelated to this issue but on reflection can shed indirect light on it.

The Analogy of the Theoretical Automobile Driver

One of the best remembered points in my exposition was the use of an analogy designed to warn against mistaking theoretical variables and their links for realistic descriptions of observable processes. This was the analogy of the "theory of overtaking" automobiles on the highways [21, pp. 534-35].

Analogies are often misleading, but in this particular case it served its main purpose: to show that the theoretical variables need not be estimated and the theoretical equations need not be solved through actual calculation by the actors in the real world whose idealized types are supposed to perform these difficult operations in the models constructed for the explanation of recorded observations.² The critics of marginal analysis believed they had refuted it if they could show that the exact numerical calculations of marginal magnitudes—cost, revenue, productivity—were difficult or impossible to perform by real decision-makers.

Yet, my analogy was only partially successful. An implication which should have been obvious has been widely overlooked: that the type of action assumed to be taken by the theoretical actor in the model under specified conditions need not be expected and cannot be predicted actually to be taken by any particular real actor. The empiricist's inclination is to verify the theoretically deduced action by testing individual behavior, although the theory serves only to explain and predict effects of mass behavior.

We may illustrate this again by means of the same analogy, the theory of overtaking. Assume a change of driving conditions occurs, say, that the roads have become wet and slippery and fog has reduced visi-

² The theoretical automobile driver had to estimate, among other things, the speeds of three vehicles and the distances between them, and to perform calculations involving potential acceleration and a few other things, before he could decide to overtake the truck ahead of him. An actual driver simply "sizes up" the situation and goes ahead.

bility. Theory enables us to predict that traffic will be slower and accidents more frequent, but it does not enable us to predict that any particular driver will drive more slowly or have an accident. The model of the reactions of the individual driver was not designed to explain the actual driving of any particular operator but only to explain the observable consequences of the observed change of conditions by deducing from the model the theoretical reactions of a hypothetical driver.

Our analogy can also show us the limitations of the model: the prediction will hold only if there is a large number of automobiles on the road. If only a very few cars are around, there may be no accident and there need not be a reduction in their speed. Conceivably, the operators may all be good and self-confident drivers. Marginal analysis of hypothetical driver reaction will suffice for explaining and predicting the consequences of a change in driving conditions if the number of automobiles on the highways is large. If the number is small, behavioral research will be needed, though it may or may not be worth the cost.

Still another use can be made of our analogy: to show the vast differences in the scope of questions to which answers can or cannot be expected with the aid of a given theory, for example, from the theory of overtaking as sketched in my article. Compare the following four questions: (1) How fast will traffic move? (2) How fast will the automobile driven by Mr. X move? (3) How will the speed of traffic be affected by fog? (4) How will the speed of Mr. X's driving be affected by fog?

The theory sketched by me offers no answer to the first question, because each of the variables specified may have very different values for different cars and drivers; it has no answer to the second question, and only a suggestion, a rebuttable presumption, for answering the fourth question, because the theory is not really concerned with particular persons or their actions and reactions. The theory is equipped only to answer the third question, regarding the effects of a change in driving conditions on automobile traffic in general, and even this answer will be qualitative only, without good clues to numerical results. It may be interesting to get answers to all four questions, but since Question 3 can be answered with a fraction of the information that would be needed to answer the other questions, it would be foolish to burden the models designed for Question 3 with irrelevant matters, or to reject such models because they cannot do what they are not designed to do.³

³ A behavioral theory of automobile driving would probably study the process by which the decision to pass a truck is arrived at in a sequence of bickering among the members of the family: Mama and Sis trying to argue against taking an unnecessary risk, Sonny egging on his Dad to speed up and pass the truck "crawling" ahead of them. Moreover, the theory would not be satisfied with "explaining" the decision to overtake but it would

Confusion of Purposes

The same sort of confusion about the scope of problems and models for their solution has been fostered in recent writings on the theory of the firm: models have been condemned or rejected because they could not be used for purposes for which they had not been designed, and significant differences in the questions to be answered have been obscured or underemphasized.

Let us again pose four typical questions and see which of them we might expect to answer with the aid of "price theory." (1) What will be the prices of cotton textiles? (2) What prices will the X Corporation charge? (3) How will the prices of cotton textiles be affected by an increase in wage rates? (4) How will the X Corporation change its prices when wage rates are increased?

Conventional price theory is not equipped to answer any but the third question; it may perhaps also suggest a rebuttable answer to the fourth question. But Questions 1 and 2 are out of reach. We could not obtain all the information that would be required for their answers and there is, therefore, no use burdening the models with variables remaining silent and inactive throughout the show.

We ought to guard against an easy misunderstanding of our denial that conventional price theory can predict actual prices of specified goods. Prediction of future prices of a particular commodity may in fact be quite manageable if we know its present price. It should be obvious, however, that this is Question 3, not Question 1. Or, one may be able to predict prices on the basis of good information on production cost. But this presupposes that we know the demand for the commodity and assume it will remain unchanged; which again comes down essentially to evaluations of changes of some variables with others held constant, that is, to Question 3.

If the number of firms producing cotton textiles is large and the X Corporation does not supply a very large part of the aggregate output of the industry, price theory may suggest an answer to Question 4, although this is not the purpose of the theory and there may be a considerable chance for the suggested answer to be wrong. The point is that a model of a theoretical firm in an industry consisting of a large number of firms can do with a much smaller number of assumptions, provided the model is used to predict, not the actual reactions of any one particular firm, but only the effects of the hypothetical reactions of numerous anonymous "reactors" (symbolic firms). If it were to be applied to ~~predictions of reactions of a particular firm~~, the model would have to

also wish to determine the speed of driving, the frequency and length of stops at roadside stands, and all the rest.

be much more richly endowed with variables and functions for which information could be obtained only at considerable effort and with results that may or may not be worth the cost of the required research.

My charge that there is widespread confusion regarding the purposes of the "theory of the firm" as used in traditional price theory refers to this: The model of the firm in that theory is not, as so many writers believe, designed to serve to explain and predict the behavior of real firms; instead, it is designed to explain and predict changes in observed prices (quoted, paid, received) as effects of particular changes in conditions (wage rates, interest rates, import duties, excise taxes, technology, etc.). In this causal connection the firm is only a theoretical link, a mental construct helping to explain how one gets from the cause to the effect.⁴ This is altogether different from explaining the behavior of a firm. As the philosopher of science warns, we ought not to confuse the *explanans* with the *explanandum*.

Misplaced Concreteness

To confuse the firm as a theoretical construct with the firm as an empirical concept, that is, to confuse a heuristic fiction with a real organization like General Motors or Atlantic & Pacific, is to commit the "fallacy of misplaced concreteness." This fallacy consists in using theoretic symbols as though they had a direct, observable, concrete meaning.

In some fields, investigators are protected from committing the fallacy, at least with regard to some of their problems, by the fact that a search for any empirical counterpart to the theoretical construct seems hopeless. Thus, some physicists working on particle theory were able

⁴ The same statement can be made about the household. The "household" in price theory is not an object of study; it serves only as a theoretical link between changes in prices and changes in labor services supplied and in consumer goods demanded. The hypothetical reactions of an imaginary decision-maker on the basis of assumed, internally consistent preference functions serve as the simplest and heuristically satisfactory explanation of empirical relationships between changes in prices and changes in quantities. In other words, the household in price theory is not an object of study.

Behavioral studies of real households are something entirely different. A realistic, behavioral theory of the household might conceivably distinguish the large, children-dominated household from a simpler, father-dominated one. The decisions in the children-dominated household, where mother frequently and father occasionally try to exercise some influence, are probably not consistent, since different preference systems are made explicit at various times, with varying decibels and gestures deployed to make them prevail over the preferences of other members of the family.

One can imagine studies on the behavior of particular households selected at random or in structured samples. If the researcher learns that a spoiled brat in a family wants to eat nothing but beef and throws a tantrum every time his mother tries to feed him other kinds of meat, a reduction in the price of chicken will probably not substantially increase the consumption of chicken in this family. Thus, the weight of the child's taste in the decision process of the family can explain a low elasticity of its demand for chicken. But none of this has much bearing on general price theory.

to answer the question "Does the Neutrino Really Exist?" [11, pp. 139-41] laconically with "Who cares?" and to explain that any belief in the "real existence" of atoms, electrons, neutrinos, and all the rest, would hold up the progress of our knowledge. Some biologists working in genetics warned, after empirical genes were discovered, that these "operational genes" should not be confused with the "hypothetical genes," which had been useful constructs in explanatory models before the discovery of any empirical referents [42, p. 814]. Economists, however, know for sure that firms exist as empirical entities and, hence, they have a hard time keeping the theoretical firm and the empirical firm apart.

For certain economic problems the existence of the firm is of the essence. For example, if we study the size distribution of firms or the growth of the firm, the organization and some of its properties and processes are the very objects of the investigation. In such studies we insist on a high degree of correspondence between the model (the thought-object) and the observed object. For other problems, however, as for problems of competitive-price theory, any likeness between the theoretical construct of the firm and the empirical firm is purely coincidental.

Economists trained in scientific methodology understand this clearly. I might quote a dozen or more writers, but will confine myself to one quotation, which states that "in economic analysis, the business firm is a postulate in a web of logical connections" [15, p. 196]. Let me add the statement of another writer, who however was plaintiff rather than advocate when he wrote that "It is a fascinating paradox that the received theory of the firm, by and large, assumes that the firm does not exist" [45, p. 249].

Here is what I wrote on one of the several occasions when I have discussed this problem:

... the firm in the model world of economic micro-theory ought not to call forth any irrelevant associations with firms in the real world. We know, of course, that there are firms in reality and that they have boards of directors and senior and junior executives, who do, with reference to hundreds of different products, a great many things—which are entirely irrelevant for the microtheoretical model. The fictitious firm of the model is a "uni-brain," an individual decision-unit that has nothing to do but adjust the output and the prices of one or two imaginary products to very simple imagined changes in data [26, p. 133].

I went on, of course, to say that this purely fictitious single-minded firm, helpful as it is in competitive-price theory, will not do so much for us in the theory of monopoly and oligopoly. To explain and predict price reactions under monopoly and oligopoly we need more than the

construct of a profit-maximizing reactor.⁵ I shall come back to this after discussing the demands for "more realistic" assumptions where they are plainly irrelevant and therefore out of place.

Realistic Models of the Firm under Competition

Many of the proponents and protagonists of a more realistic theory of the firm are quite aware of the fact that the managerial extension and enrichment of the concept of the firm was not needed except where firms in the industry were large and few, and not under the pressure of competition. There are many very quotable statements to this effect.⁶

Too many students, however, want a realistic model of the firm for all purposes. They forget the maxim of Occam's Razor that unnecessary terms in a theory be kept out (or shaved off). These students seem to miss in a simplified model the realistic trimmings of the observable world; they distrust such a model because it is obviously

⁵ You may wonder whether I have changed my mind on these matters. Incidentally, I hold that it is important for scholars and scientists to have an open mind, and the only evidence showing that they do are instances in which they have actually changed their minds. On this particular issue, however, I cannot oblige. Whether I am right or wrong, I have been consistent regarding these points. Let me quote from an article I wrote 28 years ago: "The problem of oligopoly is by definition the problem of the effects of the actions of few, giving a greater importance to the behavior of each member of the group. . . . The theory of the oligopoly price involves an interpretation of the significant motives behind the actions of a small number of people. . . . Even the most superficial theory will have to include many more ideal types of behavior in order to handle the problem of *few* sellers than it takes to handle the problem of a *mass* of competitive sellers" [20, p. 235].

On the other hand, I must plead guilty to a charge of the same error of misplaced concreteness against which I have just warned. It occurred in a sentence in which I spoke of various magnitudes (subjectively) "perceived or fancied by the men whose decisions or actions are to be explained (the business men) . . ." [21, p. 521]. If this sentence referred only to oligopolistic or monopolistic behavior, it would not be so bad, for, as I said above, the theoretical constructs of decision-makers in this case have a closer correspondence to real businessmen than the constructs in the theory of competitive prices. But the sentence was supposed to apply to the constructs of the firm in any position whatever. Hence it was a misleading sentence in that (1) it gave the impression that the decision-makers in question were *real* men (real businessmen, whom you could interview) and (2) it said that the actions of these men were to be explained, whereas the purpose of the theory was not to explain observed actions but only observable *results* of imagined (postulated) reactions to observable events.

I apologize for this error. Not that I do not approve of a busy shuttle-traffic between the domain of theoretical construction and the domain of empirical observation, but we must never fail to specify the side of the frontier on which we happen to be. The theoretical terms may have empirical referents (counterparts), but to believe, or allow an impression of belief, that the two are identical is a methodological fallacy.

⁶ "When the conditions of competition are relaxed . . . the opportunity set of the firm is expanded. In this case, the behavior of the firm as a distinct operating unit is of separate interest. Both for purposes of interpreting particular behavior within the firm as well as for predicting responses of the industry aggregate, it may be necessary to identify the factors that influence the firm's choices within this expanded opportunity set and embed these in a formal model" [48, pp. 2-3].

"descriptively false." In view of this sentimental hankering for realism, it may be helpful to survey some of the inclusions which various writers have proposed in order to meet the demands for greater realism in the "theory of the firm," and to examine their relevance to the theory of competitive price. The following considerations are supposed to supplement, qualify, restrict, or replace the objective of maximizing money profits.

(1) Entrepreneurs and managers cannot be expected to have an inelastic demand for leisure; indeed, one must assume that this demand is income-elastic so that higher profit expectations will cause them to sacrifice some income for the sake of more leisure [36, p. 356]. (2) Managers are anxious to avoid resentment on the part of their colleagues and subordinates and will, therefore, not enforce their orders with the sternness required for maximization of profits; similarly, minor functionaries do not want to disturb the routines of their superiors and, hence, they often abstain from suggesting improvements which would maximize profits [31, p. 452]. (3) Managers are more interested in their own salaries, bonuses, and other emoluments, than in the profits of the firm or the income of its owners [27, pp. 226-27]. (4) The realization of certain asset preferences (for example, liquidity as against inventories and fixed assets) may be in conflict with profit maximization [5, p. 99]. (5) The flow and biased screening of information through the various levels of management may cause systematic misinformation resulting in earnings far below the maximum obtainable [27, p. 229]. (6) The objective of maintaining control in the hands of the present control group may require a sacrifice of profit opportunities [31, p. 455]. (7) The preference for security may be so strong that even relatively conservative ways of making higher profits are eschewed [12, pp. 270-71]. (8) The striving for status, power, and prestige may be such that it results in conduct not consistent with a maximum of profit [1, p. 145] [28, p. 207] [13, p. xii] [27, p. 227]. (9) The wish to serve society, be a benefactor, or soothe one's social conscience, may militate against actions or policies that would maximize profits [7, pp. 16-17] [13, pp. 339-40]. (10) The instinct of workmanship [46, p. 187], a desire to show professional excellence [1, p. 146], a pervasive interest in feats of engineering, may lead to performance in conflict with highest possible profits. (11) Compromises among the different goals of executives with different interests—production, sales, personnel relations, finance, research and development, public relations, etc.—are sure to "compromise" the objective of maximum profits [10, p. 29]. (12) A variety of influences may be exerted on management decisions, perhaps pulling in different directions and possibly away from maximum profits, as for example influences from labor organizations, suppliers of materials,

customers, bankers, government agencies [13, p. 340] [12, p. 270] [28, pp. 195-205].

I shall not prolong this catalogue even if it is far from complete. Let us admit that each of the possible deviations from maximum profit may be "real" in some circumstances. But how effective and significant are they? If the industry is effectively competitive—and it does not have to be "purely" competitive or "perfectly" competitive—is there much of a chance that the direction in which firms react, through their decisions regarding prices, inputs and output, to a change in conditions would be turned around by any of the "forces" listed? Before we say apodictically no, we should examine a few of the reservations.

Security and Managerial Coordination

Let us single out two items which have been given especially wide play: the "objective of security" and the question of "managerial coordination."

The demand for the recognition of a separate "security motive" conflicting with the profit motive deserves a good discussion. But when I prepared for it, I reread what I had written on this subject and found that I could not improve on it. Will you do me the favor of reading it [23, pp. 51-53 and 424-28] and, if you like it, make your students read it?

That there are no business profits without risks and that there is not much point in treating the two quite separately; that it would be silly to call a decision one of profit-maximizing if it increased risk and uncertainty so much as to reduce the chance of survival; that the notion of long-run profits comprises all considerations of risks of loss; that, in terms of my automobile-driving analogies, only a fool would assume that maximization of speed means driving 120 miles an hour regardless of curves and bumps; these are some of the things that have to be said in this connection. But the most essential point to be made is that in the economics of *adjustment to change* the issues of security, survival, and maximum profit are merged. How primitive again to confuse new ventures and daring moves with mere responses to stimuli, obvious reactions to change. If a change in conditions calls for a certain reaction in the name of maximum profits, the very same reaction is called for also in the name of security of survival.

The other matter is of a more "behavioral" nature: the coordination of different goals and judgments on the part of different members of the management and the deviations from profit maximization that may be involved in the process. Frankly, I cannot quite see what great difference organizational matters are supposed to make in the firm's price reactions to changes in conditions. Assume, for example, the import duties on foreign products competing with the products of domes-

tic industry are raised, with a resulting increase in the demand for the products of the firm. Why should the clashes and compromises of divergent opinions reverse the direction of the change that would be "dictated" by the simple rule of profit maximization? Perhaps one vice president wants to raise prices without increasing output, while another wants to increase output without (at least at the moment) raising prices. No matter what their compromise will be, it is likely to conform with what the simple rule suggests. But if not, so what? Remember we are talking about industries with more than a few firms and with free entry.⁷

Other Qualifications to Competitive Price Theory

Substitution between income and leisure looks like the strongest reason for a qualification in cases in which the change in conditions is such that not only the locus of maximum profits is shifted but also the amount of profit obtainable is changed. Take again the example of a tariff increase shutting out foreign competition. The firms in the industry will find that given outputs will now fetch higher prices and that increased outputs can be sold at prices higher than those prevailing before tariffs were raised. And profits will be higher in any case, so that managers—even owner-managers—will be inclined to relax their efforts. Yet would anybody seriously argue that the substitution of leisure (coffee breaks, cocktail parties, golf) for potential profits would be such that total output would be reduced instead of increased? It is not a likely story, and where the industry consists of several or many firms, the small probability vanishes quickly. What remains of the argument is that total output would increase, in reaction to the tariff increase, somewhat less than it would if the managers were eager beavers and did not relax in their efforts when profits increased. Thus, the elasticity of supply of the products in question is a little smaller. But since we do not know how much it would be anyhow, the unknown subtraction from an unknown number should not cause the economic theorist any serious anxieties. (And if the politicians who push for the tariff increase decide to push less hard if we tell them that their friends in the industry will enjoy some of the added protection in the form of more leisure and recreation, we would not really mind.)

Even if formal accuracy demanded that we accept the maximization of the decision-maker's total utility as the basic assumption, simplicity and fruitfulness speak for sticking with the postulate of maximization of money profits for situations in which competition is effective. The question is not whether the firms of the real world will *really* max-

⁷ A great champion of more realistic theories of the firm summed up his reflections on their implications for general economics with this statement: "We shall not be far wrong in concluding . . . that the impact of more realistic theories of the firm on static price analysis is likely to be small" [6, p. 42].

imize money profits, or whether they even *strive* to maximize their money profits, but rather whether the *assumption* that this is the objective of the theoretical firms in the artificial world of our construction will lead to conclusions—"inferred outcomes"—very different from those derived from admittedly more realistic assumptions.

The second qualification in my list—regarding bosses, colleagues and subordinates—is quite irrelevant, except perhaps for questions of welfare economics, where it matters whether firms "really" do all they can to maximize efficiency. For theories concerned with *changes* in prices, inputs, and outputs in response to *changes* to conditions (of production, resource availability, and product demand) the strictness with which efficiency is watched in the firm does not matter. The effects of the tariff increase in our illustration, or the effects of changes in wage rates, interest rates, tax rates, and so forth, are if there is effective competition, essentially independent of the relations among the various levels in the managerial hierarchy of the firm.

It would take too much time here to go through our entire list of reservations. Anybody who makes the effort will find that some of the "realistic assumptions" proposed for inclusion in the theory can affect (by an unknown amount) the magnitude but not the direction of any change that is likely to result from a specified change in conditions; and that other assumptions will not even do that much. In short, they are all irrelevant for purposes of competitive price theory.

Oligopoly, Monopoly, and Managerial Discretion

I repeat: In the theory of competitive price the "real existence" of firms is irrelevant; imaginary (postulated) agents pursuing a simple (postulated) goal react to assumed changes in conditions and thereby produce (or allow us to infer) changes in prices, inputs, and outputs [24, pp. 13-14]. The correspondence between these inferences (deduced changes) and actual observations (observed changes in prices, inputs, and outputs, following observed changes in conditions) is close for two reasons: (1) The number of firms in the real world is so large that it suffices if some of them react as posited by the theory; and (2) the profits of firms are only about "normal," that is, excess profits are about zero, because of competitive pressures from newcomers (oligopolistic pressures [23, pp. 211-23]), so that profits below the maximum obtainable would in fact be net losses in an economic sense.

These two reasons do not hold in the theories of oligopoly and monopoly price.⁸ For these theories the real existence of firms (that is, an

⁸ The idea that profit maximization is the appropriate hypothesis for the theory of competitive price but not necessarily for the theory of monopoly or oligopoly price has been expressed repeatedly over the last century.

Pareto, for example, said that "pure economics" cannot tell us anything about the con-

empirical counterpart to the theoretical construct) is required, because the explanation of changes in prices, inputs, and outputs is at the same time an explanation of decisions of some particular firms, in the sense of organizations of men acting in particular, sometimes unpredictable, ways. Various attempts have been made to develop patterns of oligopolistic and monopolistic conduct and to correlate these patterns with types of organization or with types of personalities exercising ultimate decision-making power. The success has thus far been small; even if the decision-making (say, pricing) in a particular firm was sometimes satisfactorily modeled (for example, in a simulated computer program), the model has usually not been transferable to other cases, to predict decisions in other firms. I do not recall, moreover, that the behavior patterns in these cases were shown to be inconsistent with the postulate of profit maximization.

Under these circumstances, retreat to simpler, less realistic models of firms in oligopoly and monopoly positions is indicated. The first approach is to apply the polypolistic model, in full awareness that the actual facts are entirely different. In many instances the use of the polypolistic model for situations which in our judgment would merit to be labeled as oligopolistic will still yield satisfactory explanations and predictions. Where this is not so, the analyst will resort to the use of models of oligopolistic or monopolistic firms, postulating the simplest possible pattern of action and reaction, dispensing with all peculiar attitudes and "special" strategies. Only where these simple models of oligopolistic and monopolistic firms yield quite unsatisfactory predictions will the analyst need to go further, to more special types of behavior, provided he finds it worth while. It depends on the research interests and on the problems under examination how much effort one wishes to invest in behavioral research where the findings hold little promise of yielding generalizations of wide applicability.

There are, however, some simple models of oligopolistic behavior

tinuing shifts of position of competing oligopolists, and we have to turn to "the observation of facts," which would show us the variety of possibilities [29, pp. 601-2].

Schumpeter, in 1928, had this to say about the dichotomy: "We have much less reason to expect that monopolists will . . . charge an equilibrium price than we have in the case of perfect competition; for competing producers *must* charge it as a rule under penalty of economic death, whilst monopolists, although having a *motive* to charge the monopolistic equilibrium price, are not forced to do so, but may be prevented from doing so by other motives" [33, p. 371].

Finally, Scitovsky in 1951 stated that "not only does the monopolist's secure market position enable him to relax his efforts of maximizing profit, but his very position may prevent his aiming at maximum profit. He may regard his immunity from competition as precarious or be afraid of unfavorable publicity and public censure; and for either reason, he may judge it wiser to refrain from making full use of his monopoly position. We conclude, therefore, that although in some cases the monopolist will aim at maximizing his profit . . . in other cases—which may well be the important ones—he will refrain from maximizing profit" [37, p. 377].

which seem to be of sufficiently wide applicability. A model that equips the oligopolistic decision-maker not under heavy competitive pressure with an objective of gross-revenue ("sales") maximization, subject to the constraint of satisfactory net-revenue ("profit") [2, p. 49], succeeds in explaining the lack of response to some cost-increasing events observed in several instances. There are other simple models explaining the same phenomenon, and one may think of good reasons for finding one model or another more satisfactory. If the sales-maximization hypothesis can explain a greater variety of observed responses or nonresponses than other hypotheses can, and if it seems to correspond better with self-interpretations offered by interviewed businessmen, it merits acceptance, at least for the time being.

An alternative to the maximization of sales is the maximization of the growth rate of sales [3, p. 1086]. This hypothesis is especially interesting because it involves an endogenous relation with profits: while some of the growth of gross revenue may encroach on profits, it does so with an automatic limit in that profits are needed to finance the investment required for the growth of sales.

Another extension of the objective function proposed on the basis of behavioral research combines two managerial preferences for specific expenses of the firm with the usual profit motive. The two additional motives are expenditures for staff personnel and expenditures for managerial emoluments; both figure prominently in the utility functions of executives of companies which, sheltered from competitive pressures, make enough profits to allow management to indulge in these personal desires [48, pp. 38-60].

All these "managerial-discretion models" are simple and sufficiently general to allow relatively wide application. We shall have more to say about them later.

Effective Competition and Managerial Discretion

In mapping out the area of applicability for theories of managerial discretion, we have spoken of "oligopoly," "monopoly," and of "firms not under heavy competitive pressure." These are rather vague guideposts, but unfortunately the literature has not been very helpful in ascertaining precisely what it is that allows or restricts the exercise of wide managerial discretion.

Some writers stress the size of the firm, suggesting that it is only in the *large* firm that management can exercise discretion. Others stress the condition of *diffused ownership* as the one that affords management the opportunity of pursuing objectives other than maximization of profits. Those who stress oligopoly as the domain for which objective functions richer than profit maximization are needed are usually not quite specific as to their criterion of an oligopoly position: it may be

fewness of firms active in the same industry, or the subjective state of awareness of the *interdependence of price making* often characterized as "conjectural variation," or simply the *absence of aggressive competition for increasing shares in the market*. Others again stress *closed entry*, or absence of newcomers' competition, as the essential condition for a profit level sufficiently comfortable to allow managers to indulge in the satisfaction of objectives other than maximization of profits.

To combine all these conditions would probably be far too restrictive; it would confine the application of managerial-discretion models to large firms with diffused ownership, few competitors, full awareness of interdependence in pricing, absence of aggressive efforts by existing competitors to increase their market shares, and little danger of new competitors entering the field. The size of the firm may actually not be relevant, and diffused ownership may not be a necessary condition for some deviations from profit maximization to occur, say, in the interest of larger sales or larger expenditures for staff. Fewness of competitors may be more significant, chiefly because the danger of newcomers' competition is likely to be small where the number of firms has been few and continues to be few; partly also because the few competitors may have learnt that aggressive price competition does not pay. The essential conditions, it seems to me, are these two: that no newcomers are likely to invade the field of the existing firms, and that none of the existing firms tries to expand its sales at such a fast rate that it could succeed only by encroaching on the business of its competitors.

Competition from newcomers, from aggressive expansionists, or from importers is sometimes called "heavy," "vigorous," or "effective." The simplest meaning of these adjectival modifiers is this: a firm is exposed to heavy, vigorous, or effective competition if it is kept under continuing pressure to do something about its sales and its profits position. Under this "competitive pressure" the firm is constantly compelled to react to actual or potential losses in sales and/or reductions in profits, so much so that the firm will not be able to pursue any objectives other than the maximization of profits—for the simple reason that anything less than the highest obtainable profits would be below the rate of return regarded as normal at the time.

I am aware of a defect in this definition: its criterion is lodged in the effect rather than in an independently ascertainable condition. Perhaps, though, "effective" is quite properly defined in this fashion, namely, by whether certain effects are realized: competition is effective if it continually depresses profits to the level regarded as the minimum tolerable. What makes it effective is not part of the definition, but has to be explained by the conditions of entry, aggressive attitudes on the part of existing firms, or imports from abroad.

If my reasoning is accepted, several formulations proposed in the

literature will have to be amended. Managerial discretion will be a function, not of the independence of the management from the control of the owners, but chiefly of the independence of the management from urgent worries about the sufficiency of earnings. If one insists, one may still say that all managers are primarily interested in their own incomes. But, since it is clear that their long-term incomes are jeopardized if profits go below the acceptable rate of return, maximization of managerial incomes and maximization of profits come to the same thing if competition is effective.⁹

There can be no doubt about the fact that competition is not effective in many industries and that many, very many, firms are not exposed to vigorous competition. It follows that managerial discretion can have its way in a large enough number of firms to secure wide applicability of well-designed managerial-discretion models—or to invite the use of managerial total-utility models.

I was fully aware, when I wrote my 1946 article, that there were many qualifications and exceptions to the principle of profit maximization.¹⁰ But I considered it hopeless for predictive purposes to work with total-utility maximization and I did not see the possibility of combining a few selected managerial goals with the profit motive.

Marginalism Extended: Total Utility

In order to show how hopeless it is to construct a comprehensive total-utility model and obtain from it definite predictions of the effects of changes in conditions upon the dispositions of the managers, one merely has to visualize the large variety of possible "satisfactions" and the still larger variety of things that may contribute to their attain-

⁹ For competition to be effective it is not necessary that competition is either pure or perfect or that all or any of the markets in which the firm buys or sells are perfect.

¹⁰ Several of my statements, if I presented them without source reference, might well be mistaken for quotations from critics of marginalism, including behavioralists and managerialists. Here are samples [21]: ". . . a business man is motivated by considerations other than the maximization of money profits"; "it is preferable to separate the non-pecuniary factors of business conduct from those which are regular items in the formation of money profits" (p. 526); "one may presume that producing larger production volumes [or] paying higher wage rates . . . than would be compatible with a maximum of money profits may involve for the business man a gain in social prestige or a certain measure of inner satisfaction"; "it is not impossible that considerations of this sort substantially weaken the forces believed to be at work on the basis of a strictly pecuniary marginal calculus"; for patriotic reasons during the war "many firms produced far beyond the point of highest money profits"; "the conflict of interests between the hired managers and the owners of the business" may call for "important qualifications" (p. 527); "the interest of the former in inordinately large outlays or investments may be capable of descriptions in terms of a pecuniary calculus, but it is not maximization of the firm's profits which serves here as the standard of conduct" (pp. 527-28); "maximization of salaries and bonuses of professional managers may constitute a standard of business conduct different from that implied in the customary marginal analysis of the firm"; and "the extent to which the two standards would result in sharply different action under otherwise similar conditions is another open question in need of investigation" (p. 528).

ment. The satisfactions consist not only in receiving money incomes, immediate or deferred, and various incomes in kind, but also in distributing incomes to others and in gaining prestige, power, self-esteem, as well as in enjoying a good conscience and other pleasurable feelings.

What makes things really complicated is that the creation of these satisfactions is related to very different flows of funds into and out of the firm: some to gross revenue (sales volume), others to net revenue; some to profits distributed, others to profits retained; some to investment outlays, others to company expenses. The managers' immediate money incomes and some of the emoluments received in kind are partly at the expense of profits, partly at the expense of corporate income taxes (and every change in tax rates changes the trade-off ratios.) The same is true of several other company expenses which add to the prestige, power, and self-esteem of the managers. Special mention may be made of the provision of stock options for managers, which are either at the expense of the owners' equity (through watering down their stock) or at the expense of potential capital gains on treasury stock earmarked for such stock options, but which, on the other hand, may be a powerful force aligning the managers' personal interests with the goal of maximizing the net profits of the firm.

The point of it all is that the total utility of managers can be increased by decisions which increase expenses at the expense of profits. (Of course, this is confined to situations where profits are high enough to stand encroachments by avoidable expenses—to situations, that is, where the firm is not hard-pressed by competition.) The question is how various changes in conditions will affect managerial decisions on inputs, outputs, and prices if the objectives of management include the gratification of preferences for certain expenses of the firm that compete with the maximization of profits.¹¹

¹¹ Instead of cataloguing the various contributions to the "utility" of the management and their relationships to the sources and uses of the firm's funds, one may wish to classify the expenses of the firm with reference to "discretionary" decisions of the management influenced by the decision-makers' preferences. Here is a tentative classification of this sort:

1. Expenses required for the production of (a) current output of unchanged size, (b) additional current output, with marginal cost not exceeding marginal revenue (hence, contributing to higher profits), and (c) additional current output, with marginal cost exceeding marginal revenue (hence, reducing profits).
2. Expenses not required for the production of current output, but increasing the productive capacity or efficiency of the firm for future production.
3. Expenses for managerial personnel in the form of (a) salaries and bonuses, and (b) services rendered to them for their convenience and pleasure.
4. Expenses not required for either current or future production, but (a) expected of a profitable firm as a social service, and only slightly promoting the public image of management, (b) widely recognized as contributing to the social or national benefit and as indicative of the public spirit of the management, (c) contributing chiefly to the gratification of personal desires of supervisory and managerial personnel, and (d) largely

For purposes of illustration let us reproduce in a literary form the utility function of a management (perhaps of its "peak coordinator" [28, pp. 190-91]) in full control and confident that stockholders will not make any fuss as long as the firm makes a "normal" profit and pays out a fair share of it in dividends. Total utility, which the manager by his decisions will try to maximize, will be a function of a large number of variables, by virtue of the contributions they make to his pride, prestige, self-esteem, conscience, comfort, feeling of accomplishment, material consumption, and anticipations of future benefits and pleasures. Among the variables may be total profits of the firm, growth rate of profits, rate of profits to investment, total sales, growth rate of sales, increase in market share, dividends paid out, retained earnings, increase in market value of stock, price-earnings ratio of stock, investment outlay, salary and bonus received, stock options received (capital gains), expense accounts (consumption at company expense), services received (automobile, chauffeur, lovely secretary, theatre tickets, conferences at resorts), size of staff, expenses for public relations and advertising, expenses for research and development, technological and other innovations, leadership in wage increases and good industrial relations, expenses for public or private education and health, other contributions to public interest and patriotic causes, free time for leisure and recreation, and indications of influence over government, industry, and society. This list of variables is, of course, only representative, not exhaustive.¹²

Now what can one do with a utility function of this sort? Will it be of much use in telling us what the firm will do with its freedom of action if it has to respond to a change in conditions?

The answer will depend partly on a simple condition, namely, whether the acceptable trade-off ratios between all the factors contributing to total utility remain unchanged, or approximately the same, if any one of them, say, total profit, increases. If this were the case, we could shout hurrah or sigh a sigh of relief (depending on our temperament). For, if the marginal rates of substitution among all the various "utilifactors" are constant, the distribution of funds among them will remain unchanged with changes in conditions that increase or decrease the total of funds available. Only if the cost of any of the factors

wasteful, that is, contributing nothing, and economizing nothing but managerial effort or capability.

This list may be suggestive of the actions that may have to be taken when, after years of ease and growth, the firm finds its profits declining or disappearing.

¹² Perhaps there ought to be a place on the list for some gratifications that are more stable, less subject to quantitative variation, such as the pleasure of being known for honesty and fairness, on the one hand, and for sharpness and shrewdness, on the other, or at least the pleasure of being convinced of having and exercising these qualities. And last, though not least, there is the general feeling of gratification from running a large, well-known profitable, widely respected firm with growing assets and employment.

changed, say, the cost of staff personnel and, hence, the cost of prestige and other benefits that accrue from having a sizable staff, would the marginal rates of substitution be adapted to the new cost relation. In such a case we might also perhaps be able to tell the kind of response of the decision-makers.

Alas, the condition that the marginal rates of substitution are independent of the total funds available is not likely to be satisfied; in addition, certain types of change in conditions have the bad habit of affecting at the same time funds available and relative costs of utilifactors. For example, an increase in the corporate income tax will change the trade-off ratio between expensable outlays and profits in favor of avoidable expenses.

Marginalism Extended: Choice of Maximanda

If we were interested only in a formal solution, and perhaps in a proof of "existence" of an equilibrium position, we might be satisfied with the maximization of total utility by those who effectively run the firm. If, however, we want to predict the direction of the changes which a given change in conditions is likely to bring about, then mere formalism will not be enough. For predictive purposes we need *more* to go by with the help of *fewer* variables. Maximization of money profits is certainly the simplest "objective function," but it works only in the case of firms exposed to vigorous competition. The management of a firm that makes more than enough money need not go all out to maximize profits; it can afford to do a few other things that it likes, such as serving what by its own lights it regards as the national interest or indulging in other luxuries.

Would this imply "giving up" the principle of marginalism in the theory of the profitable firm? This is chiefly a semantic question. I have been inclined to use a more extended definition. In 1946, I called marginalism "the logical process of finding a maximum" [21, p. 519]. I did not say that it had to be maximization of money profits—though I struggled hard to justify the use of profit maximization in all cases. In the meantime several writers have shown that profit maximization may not be a completely unambiguous objective, even where it is used in splendid isolation from all competing goals, in that it may refuse to yield unambiguous conclusions regarding the effects of certain changes, such as the effects of changes in profit taxes. In addition, it has been shown that several workable "objective functions" can be developed that give plausible results with a few relatively simple terms added. Any of these functions that can be maximized, with or without specific constraints, would still be a part of marginal analysis.

The choice of the *maximandum* is of course a pragmatic matter: we should prefer one that yields sufficiently good approximations to what

we consider reasonable on the basis of empirical research, with wide applicability and fruitfulness and with great simplicity. The compromise among these goals that we accept is, admittedly, a somewhat "subjective" standard of selection, but perfectly in line with the standard accepted in all scientific fields. Concessions to any one of these desiderata must be at the expense of the others.

Let us list some of the alternative *maximanda* that have been suggested and are available for our choice: Total quasi-rents over a short period of time (But how short? This is good only for a freshman course); total quasi-rents during the service-life of existing fixed assets (But is a replaceable part of a machine a fixed asset? This works only for a one-hoss shay); present value of all profits (after taxes) expected in the future, discounted at a "normal" or "competitive" rate; internal rate of return to equity; equity of controlling stockholders; present values of retained earnings; growth rate of equity; gross rate of total assets; growth rate of gross revenue (sales); gross revenue (sales), if net revenues (profits) are satisfactory (over what period of time?); salaries, bonuses, and other accruals (including services in kind) to management, over their entire lives; all accruals to management plus expenditure for staff personnel, compatible with minimum profits; all accruals to management, consistent with satisfactory profits and gradually rising prices of corporate stock; and, of course, the present values of the various combinations of flows mentioned.

Surely a much longer list could be prepared, but there is no use to this. The point should be clear: profit maximization proper may mean a variety of things—several entries apply to money profits—and in addition there are a few other *maximanda* of possible relevance. Incidentally, if profits or accruals to stockholders are not explicitly included in some of the entries, let no one believe that they are really out of the picture. No management could try to maximize its own accruals in the long run if it completely disregarded the interests of the stockholders. Hence, all *maximanda* are subject to the constraint of some minimum benefits to the owners of the business in the form of dividends, capital gains, or both.¹³

Subjective Information and the Charge of Tautology

I have a few remaining tasks, and one of them is to lay a ghost, one that has long played tricks on economists and led them astray. He has

¹³ The four "managerial" variables included in the list—sales, growth of sales, expenses for staff, and emoluments to the management—may well be the most important deviations from profit maximization, although I may easily be persuaded of the existence of other "extravagances" of management. Among the managements of our large corporations there are so many civic-minded men, bursting with social responsibility and cocksure of their ability to know what is in the national interest, that I incline to the thought that rather serious deviations from the profit motive occur in the area of virtuous striving for the so-called

done this in their discussions of the subject of information, its availability, its uncertainty, and its subjectivity. I mean, of course, information available to the "firm," and this raises the question whether we mean the firm as a purely theoretical construct or the firm as an organization of real people or anything else.

The firm as a theoretical construct has exactly the kind of information the theorist chooses to endow it with in order to design a good, useful theory. The firm as an organization of real people has the information system that it actually happens to have and which, in some instances, the management scientists (operations researchers) have succeeded in developing. For purposes of competitive price and allocation theory, it does not make much difference whether the information which we assume the firm to have concerning the conditions of supply, production, and demand under which it works is correct or incorrect, as long as we may safely assume that any *change* in these conditions is registered correctly. If we want to inquire into the effects of a change in wage rates or tax rates or something of this sort, we must of course take it for granted that the decision-makers who supposedly react to the change have taken notice of it. But whether their "previous" store of information—from which they started when the change occurred—was accurate or not will only in exceptional instances make a qualitative difference to the reactions.

This important difference between information about conditions and information about changes in conditions has eluded several writers, who shouted "tautology" when they confronted my statements about the subjectivity of information. They reasoned like this: If firms act on the basis of information which is entirely subjective, then *anything* they do may be said to follow from whatever they believe they know: hence, the assumption of subjectivism defeats any explanatory purposes. This is a sad confusion. In teaching elementary economics we ought to be able to make our students grasp the difference between the shape and position of a curve, on the one hand, and the shift of a curve, on the other. The direction of the effects which we derive from the shift is usually, though not always, independent of the shape and position of the original curve. We need not fuss about the curve reflecting "accurate information" if we only want to see what happens when the curve shifts in a certain direction.

common good. I hope I am not excessively naive if I believe that the excess profits secured through restrictions on competition are to no small extent used for what the discretionary managers believe to be worthy causes. But I see no way of formulating any hypotheses that would enable us to predict either just what the firms' outlays in the public interest will be or how they will affect total output in the long run. I suppose that Boulding's witty question, "do we maximize profit subject to the constraints of morality or do we maximize virtue subject to the constraints of satisfactory profits? [7, p. 17] was not intended to suggest an answer with empirically fertile conclusions.

Since ghosts are hardy creatures, the laying of this one will probably not constitute a once-and-for-all execution. We shall probably see him again thumbing his nose at us in the next textbook or in the next issue of one of our journals.

Imperfect Information and the Question of "Satisficing" Behavior

The same confusion sometimes encumbers the discussions about the alleged "imperfection" of knowledge available to firms for their rational decision-making [39, pp. xxiv-xxvi, 40-41, 81-83, 241-42] and the screens and blockages in "the flow of information through the hierarchies of the organization" [27, pp. 228-29]. But what can be "imperfect" about the information on, say, a tax increase? Why should it take special theories of bureaucracy to explain how the news of a wage increase "flows" through various hierarchical levels up or down or across? Yet this, and this alone, is the information that is essentially involved in the theory of prices and allocation, since it is the *adjustment to such changes* in conditions for which the postulate of maximizing behavior is employed.

One can understand, of course, how the confusion arose. The proponents of managerial analysis have the creditable ambition to reorganize firms in such a way that their managements can really, as a matter of actual fact, maximize the results of their performance, not only in adjusting to changes in conditions, but also in making the most rational arrangements on the basis of the *complete environment* in which they operate.¹⁴ Incidentally, not only "normative micro-economics," as management science has been called [40, p. 279], has this ambition; many propositions of welfare economics are also based on such presuppositions.

As a matter of fact, the interesting distinction made between "satisficing" and "maximizing" or "optimizing" behavior [39, pp. xxiv-xxvi] [40, pp. 262-65] had its origin in precisely the same issue; management, realizing the complexity of the calculations and the imperfection of the data that would have to be employed in any determination of "optimal" decisions, cannot help being satisfied with something less: its behavior will be only "satisficing." What behavior? The mere adjustment to a simple change or the coordinated, integrated whole of its activities? Evidently, only the latter is the overly ambi-

¹⁴ "Economic man deals with the 'real world' in all its complexity," says Herbert Simon [39, p. xxv]. The *homo oeconomicus* I have encountered in the literature was not such a perfectionist. Incidentally, even Simon's "economic man," two years before the ambitious one just quoted, did not have "absolutely complete," but only "impressively clear and voluminous" knowledge of the "relevant aspects of his environment" [38, p. 99]. My point is that we ought to distinguish perfect or imperfect knowledge of (a) the entire environment, (b) the relevant aspects of the entire environment, (c) the relevant changes in environmental conditions.

tious aim. The theory of prices and allocation, viewed as a theory of adjustment to change, does not call for impossible performances.¹⁵ I ask you to remember what I spelled out, twenty years ago, about the difference between exact estimates and calculations, on the one hand, and "sizing up" in nonnumerical terms, on the other [21, pp. 524-25, 534-35]. And I ask you to realize how many more good predictions can be made on the basis of the assumption that firms try to maximize their profits than on the basis of the assumption that they want no more than satisfactory profits. Take one illustration: if an easy-money policy is introduced, we expect that some firms will increase their borrowings, some firms will increase their purchases, some firms will sell at higher prices, and some firms will increase their output. But if everybody was satisfied before the change, we cannot infer any of these things. On the other hand, if we assume that firms prefer a larger profit to a smaller one, all the mentioned consequences follow from the simple model.

The Twenty-one Concepts of the Firm

Several times in this paper I have spoken of the fallacy of misplaced concreteness, committed by mistaking a thought-object for an object of sense perception, that is, for anything in the real, empirical world. My warnings might have given rise to another confusion, namely, that there are only two concepts of the firm. There are many more, and I do not wish to suppress altogether my strong taxonomic propensities. I shall offer a list of ten different contexts calling for even more different concepts, some theoretical, some more empirical.

One of my favorite philosophers, who was a past-master of the art of making fine distinctions, enumerated 13 concepts of "pragmatism" [18], 66 concepts of "nature" [19, pp. 447-56], and "a great number" of concepts of "God."¹⁶ I am sure there are at least 21 concepts of the firm employed in the literature of business and economics,

¹⁵ Suppose the government imposes a 15 per cent surcharge on all import duties. The theory of the profit-maximizing firm will without hesitation tell us that imports will decline. What will the theory of the satisficing firm tell us? "Models of satisficing behavior are richer than models of maximizing behavior, because they treat not only of equilibrium but of the method of reaching it as well. Psychological studies of the formation and change of aspiration levels support propositions of the following kinds. (a) When performance falls short of the level of aspiration, search behavior (particularly search for new alternatives of action) is induced. (b) At the same time, the level of aspiration begins to adjust itself downward until goals reach levels that are practically attainable. (c) If the two mechanisms just listed operate too slowly to adapt aspirations to performance, emotional behavior—apathy or aggression, for example—will replace rational adaptive behavior" [40, p. 263]. I admit that this is an unfair use of the theory of satisficing, but I wanted to show that everything has its place and no theory can be suitable to all problems. I suspect, however, that Simon's theory of satisficing behavior will yield neither quantitative nor qualitative predictions.

¹⁶ Lovejoy Denied Approval by Senate Group," *The Baltimore Sun*, April 1, 1951.

but I shall exercise great forbearance and confine myself to a selection. Everyone may join in the game and fill in what I leave out. I shall first state the context, then delimit the concept, and finally add a few words of explanation.

1. In the theory of competitive prices and allocation, the firm is *an imaginary reactor to environmental changes*. By "imaginary" I mean to stress that this a pure construct for which there need not exist an empirical counterpart. By "reactor" I mean to deny that this robot or puppet can ever have a will of his own: he is the theorist's creature, programmed to respond in the predetermined way.

2. In the theory of innovation and growth, the firm is *an imaginary or a typical reactor or initiator*. Depending on which theory one has in mind, we see that several combinations are possible. In the theory of "entrepreneurial innovation" by men of very special qualities [34, pp. 78-94] the entrepreneur is neither imaginary nor a mere reactor; he is a typical initiator. By "typical" I do not refer to the ideal type of German sociology [47, p. 44] [35, pp. 20-63, 81] [25, pp. 21-57], but rather to the common-sense kind of person that many of us have met in person or, at least, have heard about. On the other hand, there are also theories of "induced invention"—assuming latent inventive-ness (though an invention can never be a mere reaction)—and theories of "induced growth," employing the construct of the imaginary reactor.

3. In welfare economics, the firm is *an imaginary or a typical reactor or initiator with accurate knowledge of his opportunities*. Depending on the proposition in question, all combinations are again possible, but in any case a new requirement is introduced: accurate knowledge of the environmental conditions on the part of all reactors and initiators. For, in contrast to the theory of price and allocation, the welfare theorist wants to ascertain, not only in which direction price, input, and output will move in response to a change, but also whether this move will increase or reduce welfare. For such an exercise it is no longer irrelevant whether the subjective information of the firms is correct or false.

4. In the theory of oligopoly and monopoly, the firm is *a typical reactor and initiator in a small (or zero) interacting group*. I have explained earlier why a theory of oligopoly with nothing but imaginary reactors may not be widely applicable.

5. In the theory of organization (or bureaucracy), the firm is *a typical cooperative system with authoritative coordination*. I have accepted this formulation from one of the authorities [28, p. 187] and thus may disclaim responsibility for it.

6. In management science (or the art of business management), the firm is *a functional information system and decision-making system*

for *typical business operations*. The normative nature of management science should be stressed. Several management scientists include operations research among the agenda of management science. I take this to mean that the principal techniques of operations research of such matters as inventory problems, replacement problems, search problems, queueing problems, and routing problems have to be mastered by the management scientist. He should, however, make a distinction between the science and its application: the science deals with typical systems, but is applied to particular cases.

7. In operations research and consultation, the firm is *an actual or potential client for advice on optimal performance*. In this context the reference is not to the techniques and principles of operations research but rather to the particular projects planned or undertaken.

8. In accounting theory, the firm is *a collection of assets and liabilities*. It should be clear how different this concept is from most of the others.

9. In legal theory and practice, the firm is *a juridical person with property, claims, and obligations*. This may be a very deficient formulation; I defer to the experts, who will surely correct it.

10. In statistical description (such as the Census of Manufactures) the firm is *a business organization under a single management or a self-employed person with one or more employees or with an established place of business*. I have adopted here the definition used by the U.S. Census.

This exercise should have succeeded in showing how ludicrous the efforts of some writers are to attempt *one* definition of *the* firm as used in economic analysis, or to make statements supposedly true of "the" firm, or of "its" behavior, or what not. Scholars ought to be aware of equivocations and should not be snared by them.

A Sense of Proportion

I hope there will be no argument about which concept of the firm is the most important or the most useful. Since they serve different purposes, such an argument would be pointless. It would degenerate into childish claims about one area of study being more useful than another.

I also hope the specialist who uses one concept of the firm will desist from trying to persuade others to accept his own tried and trusted concept for entirely different purposes. The concept of the firm in organization theory, for example, need not at all be suitable for accounting theory or legal theory; and I know it is not suitable for either competitive price theory or for oligopoly theory.

Most of the controversies about the "firm" have been due to misun-

derstandings about what the other specialist was doing. Many people cannot understand that others may be talking about altogether different things when they use the same words.

I am not happy about the practice of calling any study just because it deals with or employs a concept of the firm "economics" or "micro-economics." But we cannot issue licenses for the use of such terms and, hence, must put up with their rather free use. My own prejudices balk at designating organization theory as economics—but other people's prejudices are probably different from mine, and we gain little or nothing from arguing about the correct scope of our field.

Now what conclusions from all our reviewing may we draw on the conflicts between marginal analysis, behavioral theory, and managerial theory of the firm? Fortunately, not much time is being wasted on descriptive studies of a narrowly behaviorist kind, in the sense of recording observed behavior without any prior theoretical design. Most proponents of behavioral studies of the firm are too competent theorists for that. As far as the proponents of managerial theories are concerned, they have never claimed to be anything but marginalists, and the behavior goals they have selected as worthy for incorporation into behavior equations, along with the goal of making profits, were given a differentiable form so that they could become part of marginal analysis.¹⁷ Thus, instead of a heated contest between marginalism and managerialism in the theory of the firm, a marriage between the two has come about.

Not all marriages, these days, are permanent; divorces are frequent. Whether this marriage will last or end in divorce will depend chiefly on what offspring it will produce. If the match of the profit hypothesis with the various managerial hypotheses proves fertile of sufficiently interesting deductions, the prospects of a lasting marriage are good.

It is not easy to judge the future sterility or fertility of this marriage between marginalism and managerialism, because most of us are inclined to underrate the kinds of problem on which we have never

¹⁷ While under profit maximization $MR - MC = 0$, sales maximization requires that $MR = 0$; hence, for some of the output sold marginal revenue is less than marginal cost, which cuts into profits. A minimum-profit constraint sets a limit to this.

In the case of maximization of the growth rate of sales the limit on nonremunerative selling is built into the objective itself because a growth of productive assets is required to support the growth of sales, and the acquisition of these assets presupposes a sufficiency of profits, either for internal financing or as a basis for outside finance [3, pp. 1086-87]. If at any time sales were pushed too hard at the expense of profits, there would arise a shortage of funds for acquiring the productive assets needed for producing more output. Thus no separate minimum-profit constraint has to be imposed, since it is inherent in the objective of maximization of the growth of sales. It should be understood, however, that the growth rate of assets under this objective is still less than it could be under straight profit maximization. (This shows why we should never speak of the "growth of the firm" without specifying by what criterion we measure it.)

worked: we have a bias in favor of our own research experience. Most of the researchers on behavioral versions of the theory of the firm look for their problems to the records of selected large corporations. They take it for granted that their theory must be designed to explain and predict the behavior of these firms. This, however, is less so in the case of economists engaged in the analysis of relative prices, inputs, and outputs. They look for their problems to the records of entire industries or industrial sectors. To be sure, some industries are dominated by large corporations, yet the accent of the analysis is not on the behavior of these firms but at best on some of the results of that behavior. Where the focus is not on the behavior of the firm, a theory that requires information on particular firms to be "plugged in" seems to them less serviceable than a more general theory, at least as long as only qualitative, not numerical, results are sought. Hence, even if the "partial-equilibrium analyst" knows full well that the actual situation is not a really competitive one, he probably will still make a first try using the competitive model with good old-fashioned profit maximization. And if the results appear too odd, appropriate qualifications may still be able to take care of them more simply than if he had started with a cumbersome managerial model. (In saying this, I am showing my bias.)

It is revealing to ask what kind of theory we would apply, at least in a first approximation, if we were called upon to predict the results of various kinds of public-policy measures. For questions regarding short-run effects of changes in the corporation income tax (or an excess-profits tax) I believe a strong case can be made in favor of a model of the firm with some managerial variables. If the problem is whether an increase in cigarette taxes is likely to be fully shifted onto the consumer or what portion of it may be absorbed by the producers, I may feel safer with a model that includes managerial objectives. If, however, the problem is what qualitative effects an increase in the import duty on a material used in several industries will have on its imports and on the prices and outputs of the various products of the industries in question, I would be inclined to work with the simple hypothesis of profit maximization. I would find it far too cumbersome in this case to go down to the level of the "real" firms; I could probably not obtain the necessary data and, even if I did, I might not be able to rely on the composite results obtained from a firm-by-firm analysis. The old theory of the firm, where all firms are pure fictions, may give me—in this case—most of the answers, in a rough and ready way, not with any numerical precision, but with sufficient reliability regarding the directions of change.

I conclude that the choice of the theory has to depend on the prob-

lem we have to solve.¹⁸ Three conditions seem to be decisive in assigning the type of approach to the type of problem. The simple marginal formula based on profit maximization is suitable where (1) *large groups* of firms are involved and nothing has to be predicted about particular firms, (2) the effects of a *specified change* in conditions upon prices, inputs, and outputs are to be explained or predicted rather than the values of these magnitudes before or after the change, and nothing has to be said about the "total situation" or general developments, and (3) only *qualitative answers*, that is, answers about directions of change, are sought rather than precise numerical results. Managerial marginalism is more suitable to problems concerning particular firms and calling for numerical answers. And, I am sure, there are also some problems to which behavioral theory may be the most helpful approach. My impression is that it will be entirely concerned with particular firms and perhaps designed to give answers of a normative, that is, advisory nature.

It looks as if I had prepared the ground for a love feast: I have made polite bows in all directions and have tuned up for a hymn in praise of peaceful coexistence of allegedly antagonistic positions. But I cannot help raising a question which may tear open some of the wounds of the battle of 1946. The question is whether the effects of an effective increase in minimum wages upon the employment of labor of low productivity can, at our present state of knowledge, be fruitfully analyzed with any other model than that of simple marginalism based on unadulterated profit maximization.

If I answer in the negative, does this mean that we are back at the old quarrel and have not learned anything? It does not mean this. Deficiencies in marginal analysis have been shown and recognized; and a great deal of good empirical as well as theoretical work has been accomplished. But the deficiencies dealt with were not just those which the critics twenty years ago attacked. That attack questioned the applicability of marginal analysis to the employment effects of wage increases in industries with many firms presumably under heavy competition [16, pp. 64, 75-77]. In such circumstances the managerial theories of the firm, according to their proponents, do not apply. On this narrow issue, therefore, the old-type marginalist cannot retreat.

¹⁸ As a matter of fact, it will also depend on the research techniques which the appointed analyst has learned to master; we can eliminate this bias by assuming an ideal analyst equally adept in all techniques.

SOME NEW RESULTS IN THE MEASUREMENT OF CAPACITY UTILIZATION

By L. R. KLEIN AND R. S. PRESTON*

I. Statement of the Problem

The concepts of capacity output and rate of capacity utilization have been prominent in recent discussions of U.S. economic potential. These are important descriptive concepts for the economy as a whole and merit careful attention in statistical measurement. They are also very difficult concepts to measure and are not yet well established in our economic annals. Capacity variables have been significant ingredients in the econometric models constructed at the Wharton School, and a great deal of effort has been devoted to development of a measure which would reliably serve a wide range of uses in applied econometrics [2] [6, pp. 53-59].

The Wharton School Index of capacity utilization is constructed by a very simple procedure which enables us to provide quick and frequent estimates of this useful economic statistic. Briefly, the method involves marking off cyclical peaks for each of thirty component indexes of the Federal Reserve Board's Index of Industrial Production and then fitting linear segments between successive peaks. Between the present time period and the last established peak, the previous linear segment is extrapolated at its established slope unless the index in the present period exceeds the extrapolated trend line. In this case a new slope is computed by fitting a new linear segment from the last cyclical peak to the present value of the index. Revisions will be continuously made in the last linear segments until there is a cyclical downturn in the index of industrial production. This establishes a new peak, and the process thus begins again. The trend lines through peaks, we assume, represent an index of capacity output, on a base of actual output, namely the same base as that used in the F.R.B. index.

In constructing the Wharton Series our basic data are quarterly series constructed from three-month averages of the F.R.B. seasonally adjusted monthly industry indexes [5]. A monthly index is being constructed and tested, but we shall deal here with the quarterly index. Normally, peak values must exceed immediately preceding and following quarterly values, but we must deal with some special cases. When the index of output is unchanged for two or more successive peak

* The authors are university professor of economics at the University of Pennsylvania and econometrician, department of economic research, IBM Corporation.

quarters, we choose the first of the two as the capacity peak. When output declines from a peak and then rises again, with the decline no more than one quarter in duration, the greater of the two high values is selected as a single capacity peak.

The ratio of actual output to the trend line (linear segments) fitted through peaks is called capacity utilization. For each quarter, such ratios are computed for each of the thirty component industries and then averaged, using F.R.B. index weights, to reach our economy-wide index of capacity utilization.

A principal objection to this method of estimating capacity utilization is that some peaks may be marked off as full capacity utilization peaks when in fact there may have been considerable underutilization of capacity. The objections have been summarized by A. Phillips [3] in his survey of various alternative capacity measures. To be practical and specific, the general presumption among economists is that the recovery from the 1957-59 recession was incomplete, and the subsequent peaks in many sectors represent points of substantial underutilization of capacity. The Wharton School Index of capacity utilization is therefore thought to be biased upwards since 1958-59.

It is the purpose of this study to develop an alternative measure of capacity and capacity utilization at the industry level from production functions. This is done for a sample of 11 of the 30 industries which make up the Wharton Index. We then compare the results from this newer method with those obtained by the method described above. An adjustment for those component Wharton Indexes which are found to be subject to bias drift is developed. Finally, a method is developed to adjust the aggregate Wharton Index for bias drift, based on our results of the sample of 11 industries studied.

II. *The Estimation of Capacity and Capacity Utilization From Production Functions*

Another approach to the problem of capacity estimation is by the estimation of cost or production functions by sector. In the case of cost functions, it has often been suggested that the point of minimum average cost may represent full capacity output (in a competitive environment). The estimation of cost functions, by sectors, may be a fruitful step in capacity estimation, but there is a problem in obtaining a sharply defined minimum point for empirical average cost functions.

In this study we approach the problem through the use of production functions. For each sector we define actual output by the conventional production function relationship.

$$(1) \quad X_t = Ae^{\gamma t} L_t^\alpha K_t^\beta v_t$$

where X_t is actual output at time t , L_{ut} is manhours employed at time t , K_{ut} is real capital utilized at time t , $e^{\gamma t}$ is a proxy for technical change, and v_t is the disturbance at time t .

Full capacity output is defined as

$$(2) \quad X_{c,t} = A e^{\hat{\gamma}t} L_t^{\hat{\alpha}} K_t^{\hat{\beta}},$$

where $X_{c,t}$ denotes full capacity real output at time t , L_t is available manhours at time t (in practice, frictional unemployment is allowed for), K_t is fully utilized real capital at time t , and $e^{\gamma t}$ is a proxy for technical change.

The function f is the same in (1) as in (2), apart from the fact that parameters in (1) have been replaced by their estimates in (2). The disturbance $\log v_t$ is given its expected value (zero) in (2). In our particular case, errors in estimating $X_{c,t}$ will be caused by measurement error for L_t and K_t , by misspecification of the equation, or by biased parameter estimates of (1). Assuming that L_t and K_t are measured without error, that the relationship has not been misspecified, and that our estimating method produces unbiased estimates of the parameters, we may regard $X_{c,t}$ as error free.

III. *The Estimation of Series on Utilized Capital Stock and Capacity Manhour Inputs by Industrial Sector*

Among the many time honored problems in the estimation of production functions there are two particularly thorny ones involved in the present study. It is very difficult to determine K_{ut} in (1) and L_t in (2). If there were a large number of full capacity peak points for each industry, (2) could be estimated directly from a sample of peak observations on $X_{c,t}$, L_t , and K_t . Many difficulties would thus be overcome simultaneously. We considered the possibility of making direct estimates of (2) from the very small sample of post-war full capacity peak point observations, but the smallness of the sample made the results too unstable for practical use. Equation (1) is the production function, whose statistical study was initiated by the great pioneering investigations of Paul Douglas. The problem in the present context is that capital is not fully utilized over the business cycle; therefore estimates of the stock of capital in existence (the only ones we have directly) do not furnish a suitable input variable during periods of under-capacity utilization. We do have direct estimates of X_t and L_{ut} , the latter being expressed in manhours.

If we had estimates of (1), we could compute $X_{c,t}$ as values on the production function surface corresponding to full capacity inputs of L_t and K_t . It is difficult to obtain estimates of the series K_{ut} in estimating

(1), and it is similarly difficult to obtain estimates of the series on L_t in estimating X_{e_t} from (2). Since we are estimating production functions and associated capacity values by industry, we have the difficult task of determining values of L_t for each industry.

We have an industrial distribution of actual manhour employment. From this we can aggregate and adjust this aggregate for induced labor force participation and the national rate of unemployment to arrive at an economy-wide supply of manhour series, but we do not know the supply of manhours to each sector. Such manhour data are not directly available.

Lacking estimates of capital utilization by industry, we are forced to use a proxy. Different measures have been used in previous studies, e.g., Carl Christ used the rate of new investment as such a proxy, on the assumption that new investment would be determined by the percentage of unutilized capital [1]. We have used a more direct proxy, namely the rate of manhour employment by industry. This, in concept, follows the procedure of Robert Solow [4]. It is apparent that the measurement of K_{u_t} cannot be completed until L_t is measured for each industry in our sample. Both measurement problems are tied together.

To relate capital utilization to manhour utilization, we assume, as Solow has done,

$$(3) \quad \frac{K_{u_t}}{K_t} = \frac{L_{e_t}}{L_t}.$$

Equation (3) is not an unreasonable assumption. It can be shown that this relationship in combination with the Cobb-Douglas form of the production function will enable us to relate the rate of unemployment directly to the rate of capacity utilization. In this case it can be shown that logarithms of estimated industry utilization rates are linear functions of logarithms of industry employment rates. The parameters in these relationships are those of the Cobb-Douglas production function and vary from industry to industry.

This can be seen very quickly. If we assume that the production function is Cobb-Douglas and that capacity output is defined as in (2), with K_{u_t} defined as in (3), then we find that

$$\frac{X_t}{X_{e_t}} = \left(\frac{L_{e_t}}{L_t} \right)^{\alpha+\beta} v_t.$$

For any given industry the degree of homogeneity of this function is the same as that of the production function for the industry. Increasing returns to scale in the production function would then be indirectly

supported by the observation that proportional changes in unemployment rates result in more than proportional changes in the utilization of capacity.

Although we are limited to computing production functions for only eleven sectors, our restriction being availability of capital data, the construction of series on L_t for each industrial sector, cover 31 sectors (both manufacturing and nonmanufacturing). These 31 sectors include all the industries included as component sectors of the Industrial Production Index plus all nonmanufacturing categories, except agriculture and the self-employed. As a result, the construction of series on L_t for each industrial sector involved a larger sample of sectors than the final computation of production functions. It is felt that, in the construction of L_t , as many sectors as possible should be taken into account in the aggregation to a national figure.

Our first step is to estimate full-employment (full capacity) manhours for the economy as a whole. We shall then allocate this total among sectors. Let us define (in terms of men—not manhours) L_t as total labor force at full capacity, L_{e_t} as employed labor force, L_{v_t} as involuntarily unemployed labor force, and L_{f_t} as frictionally unemployed labor force. We shall measure full capacity labor force as the value of L_t which satisfies (4), given L_{e_t} , L_{v_t} , and L_{f_t} .

$$(4) \quad L_t = L_{e_t} + L_{v_t} + L_{f_t} + \delta[L_t - L_{e_t} - L_{f_t}],$$

where δ is the coefficient of response of labor supply to employment opportunities. This makes full capacity labor force the sum of employed and unemployed persons plus an induced amount depending on the level of unemployment. We may solve (4) for L_t as follows.

$$(4a) \quad (1 - \delta)(L_t - L_{f_t}) = (1 - \delta)L_{e_t} + L_{v_t}$$

$$(4b) \quad L_t - L_{f_t} = L_{e_t} \left[1 + \left(\frac{1}{1 - \delta} \right) \left(\frac{L_{v_t}}{L_{e_t} + L_{v_t} + L_{f_t}} \right) \right]$$

so that

$$(4c) \quad L_t - L_{f_t} = L_{e_t} \{ 1 + (\mu_t - \mu_{f_t}) / [(1 - \delta)(1 - \mu_t)] \},$$

where

$$(4d) \quad \mu_t = (L_{v_t} + L_{f_t}) / (L_{e_t} + L_{v_t} + L_{f_t})$$

and

$$(4e) \quad \mu_{f_t} = L_{f_t} / (L_{e_t} + L_{v_t} + L_{f_t}).$$

We note that μ_t is equal to the total unemployment rate and μ_{ft} is equal to the frictional unemployment rate. We shall measure full employment manhours, as actual manhours used (L_{et} expressed in hours) adjusted by

$$(5) \quad 1.0 + (\mu_t - \mu_{ft}) / [(1 - \mu_t)(1 - \delta)].$$

This gives us a measure of potential manhours less frictional manhours. The above adjustment factor is observable from published employment series provided we have estimates of μ_{ft} and δ .

We choose μ_{ft} as 2.67 per cent, the low rate of unemployment observed in the record quarter of 1953. We place δ at .25, an estimate which is consistent with the labor supply equation estimated in econometric models developed at the Wharton School in which the capacity utilization indexes are intended to be used [2].

The labor supply equation estimated in [2] is

$$(6) \quad L_{et} + L_{vt} + L_{ft} = 61.2 + .226t - .310(L_{vt} + L_{ft}).$$

We can see that the coefficient of .310 in this labor supply equation suggests a value of δ in (4) of .25. Write down the above expression (4) for L_t as

$$(7a) \quad L_t = L_{et} + L_{vt} + L_{ft} + \delta(L_t - L_{et} - L_{vt} - L_{ft} + L_{vt}).$$

Rearranging terms, we find

$$(7b) \quad L_{et} + L_{vt} + L_{ft} = L_t - \left(\frac{\delta}{1 - \delta}\right)(L_{vt} + L_{ft}) + \left(\frac{\delta}{1 - \delta}\right)L_{ft}.$$

We assume that the frictional unemployment rate is a constant proportion of fully employed labor force. Thus we can write

$$(7c) \quad L_{ft} = kL_t,$$

and we can rewrite (7b) as

$$(7d) \quad L_{et} + L_{vt} + L_{ft} = \left(1 + \left(\frac{\delta}{1 - \delta}\right)k\right)L_t - \left(\frac{\delta}{1 - \delta}\right)(L_{vt} + L_{ft}).$$

The coefficient of $(L_{vt} + L_{ft})$ in (6) is therefore equal to $-\delta/(1 - \delta)$. This suggests an estimate of δ of about .25. We therefore evaluate

$$(8) \quad L_t - L_{ft} = L_{et} \left[1.0 + \frac{\mu_t - .0267}{(1.0 - \mu_t)(.75)} \right]$$

as our estimate of available manhours, where L_{et} results from the aggregation over our 31 industries in each time period.

It was found, after the series $L_t - L_{f,t}$ was computed from the series $L_{e,t}$, that this aggregate supply series still had cycles in it. This is in part due to the fact that our arguments in the previous section were carried out in terms of people and the final adjustment (8) was made to a man-hour concept. We correct this in the following fashion. On a priori grounds the aggregate supply of manhours should have no cycle, but should be a smooth monotonic increasing function of time, reflecting additions to the labor force as the economy grows. The cycle in $L_t - L_{f,t}$ may

be due to variations in overtime and short shift work which is not reflected in hiring and firing policy. At peaks of the series $L_t - L_{f,t}$ man-hour employment resulting from overtime is at its peak; therefore, by fitting linear segments through peaks we approximate the smooth monotonic increasing trend of the aggregate supply of manhours for the 31 sectors as a whole.

These results are summarized in Chart 1. In Chart 1, series 1 is full employment aggregate manhours. This series has resulted from the linear interpolation of the peaks of $L_t - L_{f,t}$. Series 2 is actual manhours, in our notation $L_{e,t}$. Series 3 is, in our notation, $L_t - L_{f,t}$.

Our problem now is to redistribute series 1 in Chart 1 over our 31 industries. In our sample of 31 industries, the distribution of employment changes over time due to changes in relative factor rewards (wage

rates), caused by shifts in demand and changes in worker tastes. The demand for a factor is a derived demand, derived from the demand for the product. With the aggregate supply function stable over time, the industry distribution of manhours is then determined by the relative importance of each sector in the production of aggregate output. We approximate the trend in *capacity input* of labor to each industry by first approximating the trend in the share each sector received of the aggregate at full employment peaks. By fitting linear segments between these computed shares we can approximate the trend in the share of total manhours used by each sector at peak demand points.

It is important to understand that these linear segments were not fitted between peaks of the individual sector series, but between the benchmark manhour shares that each industry got at points where series 2 on Chart 1 peaked. We now argue that these trend series represent the full capacity share for each of our 31 sectors at any point in time. We multiply these percentages into series 1 to arrive at the trend in capacity manhours for each of our individual sectors. Aggregate unemployment or induced labor force participation is distributed over industrial sectors in accordance with the trend in the *share* of each sector in the aggregate. As a result, these sectors whose share in the aggregate is increasing will also receive an increasing share of unemployment or induced labor force participation. Furthermore, those industries that have larger shares in the aggregate will receive larger shares of aggregate unemployment or induced participation. This, of course, is a simplifying assumption.

IV. *The Estimation of Production Functions*

We do not assume constant returns to scale and thus place no restrictions on $\alpha + \beta$. There is much evidence in favor of this procedure in the case of the American economy, although there are some investigators who impose the restriction $\alpha + \beta = 1$. If we assume cost minimization rather than profit maximization behavior, to allow for the presence of increasing returns to scale, it is possible to estimate the ratio β/α first from factor share data. Direct estimates of (1) lead to problems of multicollinearity and least squares bias. In the cost minimization equation

$$(9) \quad \frac{q_t K_{u_t}}{w_t L_{e_t}} = \frac{\beta}{\alpha} + z_t,$$

where $q_t K_{u_t}$ is nonwage income originating in period t , $w_t L_{e_t}$ is wage income originating in period t , and z_t is a disturbance in period t , we have an estimate of β/α as

$$(10) \quad \left(\frac{\hat{\beta}}{\alpha}\right) = \frac{1}{T} \sum_{t=1}^T \frac{q_t K_{ut}}{w_t L_{et}}.$$

We then estimate A , α and γ from the regression

$$(11) \quad \text{Log}_e(x_t) = \text{Log}_e(A) + \gamma t + \alpha \left[\text{Log}_e(L_{et}) + \left(\frac{\hat{\beta}}{\alpha}\right) \text{Log}_e(K_{ut}) \right] + \text{Log}_e v_t.$$

With estimates \hat{A} , $\hat{\gamma}$, $\hat{\alpha}$ and $\hat{\beta}$, where $\hat{\beta} = \hat{\alpha}(\hat{\beta}/\hat{\alpha})$, we can now compute capacity output from (2), given K_t and L_t for each industry.

Using single equation least-squares regression methods to estimate (11), we shall obtain biased estimates of coefficients, as the error $\text{log}_e v_t$ is not independent of $\text{log}_e(L_{et}) + (\hat{\beta}/\hat{\alpha}) \text{log}_e(K_{ut})$. We recognize the existence of this bias but do not take it into account in the capacity estimation procedure. The ratio of observed values of X_t to the computed values of X_{et} are our estimates of capacity utilization rates, R_t .

$$R_t = \frac{X_t}{X_{et}}.$$

V. The Method Used To Adjust The Component Wharton Indexes

Denote the individual Wharton School Indexes by Wh_t . As will be seen in Section IX, the time profile of the R_t and Wh_t series are remarkably similar. Both series deal with essentially the same phenomenon, but in some sectors the Wh_t series drifts higher than the R_t series, especially in recent years. This is the bias we are seeking to measure.

We correlate the two series to find

$$(12) \quad Wh_t = a + bR_t + ct.$$

Primarily, we are not interested in the difference in the level between Wh_t and R_t , for we think the Wh_t series establishes a reasonable level in the period before 1957. We are especially interested in the tendency of the Wh_t series to drift upwards in recent years. Therefore, where the estimated regression coefficient c is significant and positive, we assume that an element of bias has been found. The adjusted Wharton Index Wh_t^A is then computed for those industries where bias is found as

$$(13) \quad Wh_t^A = Wh_t - ct.$$

We make this adjustment to all sector Wh_t series where a significant and positive c coefficient is found.

VI. *The Method Used to Adjust the Aggregate Wharton Index*

As mentioned earlier our sample of industries studied deals only with a subgroup of those industries which make up the aggregate Wharton Index. We now develop a method which will enable us to draw a conclusion about the bias in the Aggregate Wharton Index on the basis of our sample subgroup. As mentioned earlier, this subgroup is composed of 11 industries.

Let r_i be the F.R.B. weight for the i -th industry. For the 11 industries in our sample, form (for $t=t_0$)

$$(14) \quad \frac{\sum_{i=1}^{11} r_i (Wh_i - c_i)}{\sum_{i=1}^{11} r_i} = \frac{\sum_{i=1}^{11} r_i Wh_i}{\sum_{i=1}^{11} r_i} - \frac{\sum_{i=1}^{11} r_i c_i}{\sum_{i=1}^{11} r_i},$$

$$(14a) \quad = Wh^S - \bar{c},$$

where S stands for sample subgroup. If we could do this for all industries in the index we would have

$$(15) \quad \sum_{i=1}^{11} r_i Wh_i - \sum_{i=1}^{11} r_i c_i + \sum_{i=12}^{30} r_i Wh_i - \sum_{i=12}^{30} r_i c_i = Wh^A,$$

$$\text{since } \sum_{i=1}^{30} r_i = 1.0.$$

We can combine the first and third terms to get

$$(16) \quad \sum_{i=1}^{30} r_i Wh_i - \sum_{i=1}^{11} r_i c_i - \sum_{i=12}^{30} r_i c_i = Wh^A.$$

But we do not know the last term on the left hand side

$$\sum_{i=12}^{30} r_i c_i.$$

If we assume that subgroup 1 to 11 and 12 to 30 would each give the same average correction term, we can write

$$(17) \quad \frac{\sum_{i=1}^{11} r_i c_i}{\sum_{i=1}^{11} r_i} = \bar{c} = \frac{\sum_{i=12}^{30} r_i c_i}{\sum_{i=12}^{30} r_i}$$

OR

$$\bar{c} \sum_{i=1}^{11} r_i = \sum_{i=1}^{11} r_i c_i, \quad \text{and} \quad \bar{c} \sum_{i=12}^{30} r_i = \sum_{i=12}^{30} r_i c_i.$$

As a result we can now write

$$(18) \quad Wh^A = \sum_{i=1}^{30} r_i Wh_i - \bar{c} \sum_{i=1}^{11} r_i - \bar{c} \sum_{i=12}^{30} r_i.$$

This reduces to $Wh^A = Wh - \bar{c}$, where Wh is the unadjusted 30 sector weighted average, Wh^A is the adjusted 30 sector weighted average, and \bar{c} is defined above as the mean adjustment for the 11 sectors.

We assume that the bias accumulated in the Wh_i index by 1960 terminates a tendency of the Wharton School Index to drift upwards and make adjustment after that date by the fixed amount applied to 1960.

VII. *Description of The Data*

Our basic data series used in the present study are the Federal Reserve Board's monthly index of industrial production on a 1958 base, the F.R.B. industry weights, a quarterly series on total man-hours used by each sector, a quarterly series on GNP originating in 1954 dollars for each sector, a quarterly series on fixed capital in 1954 dollars for each sector, a yearly series on national income originating for each sector, and a yearly series on wages, salaries and supplements for each sector.

Three-month averages were constructed from the monthly series (seasonally adjusted) of the F.R.B. index to yield a quarterly series of the industrial production index. For this series the sample period runs from 1947-1 to 1965-2. For all other series, the sample period runs from 1948 to 1960. The quarterly series on total manhour employment are aggregated from series on average weekly hours and average number of employees. The capital stock series is essentially a series on constant dollar net investment accumulated from an initial period estimate of the stock of capital. In the estimation of (β/α) , income of nonlabor factors was computed by a residual method, namely as national income originating minus wages, salaries and supplements.

In two cases the Federal Reserve Board's classification did not agree with our production function breakdown. These were Food and Beverages and Gas and Electric Utilities. This was remedied by computing a weighted average of Food and Beverages of the Wharton Index using F.R.B. weights and by computing a weighted average of Gas and Electric Utilities of the Wharton Index using F.R.B. weights. In nine other F.R.B. categories we have comparable data. For seventeen other F.R.B. categories we have no comparable production function data.

TABLE 1.—PRODUCTION FUNCTION COEFFICIENTS
 $X_t = A e^{\gamma t} L_t^\alpha K_t^\beta v_t'$

| | $\widehat{\log A}$ | $\hat{\alpha}$ | $\hat{\beta}$ | $\widehat{(\beta/\alpha)}$ | $\hat{\gamma}$ | \bar{R}^2 |

The 11 groupings with which we finally ended included 62 per cent of the total F.R.B. weight, including all the most important categories of the Wharton Aggregate Index.

VIII. *The Estimated Production Functions*

In Table 1 we present the estimated production functions for the 11 sectors we are dealing with in this study. In all but two industries we find that the data suggest that increasing returns to scale is the proper assumption about the degree of homogeneity of the production function. Chemicals, and Food and Beverages show decreasing returns to scale. Among all the industries studied, Food and Beverages yields the least reasonable estimate of α and β . Most of the variance of X_t is explained by a straight trend, our proxy for technical change. All the estimates of

γ are positive and significant except for Primary Metals and Paper and Allied Products, where the coefficient is not significant.

IX. *The Time Profiles of the Wh_t and R_t Series and the Isolation of the Bias Drift by Industry*

In Table 2 we give the series $R_t(1)$, the series $Wh_t(2)$ and the difference $R_t - Wh_t(3)$. Although in the isolation of the bias drift primary emphasis will be placed on the regression results, in the final analysis both the inspection of Table 2 and the regression results will play a part in determining whether a particular sector series is subject to drift.

For Primary Metals, both series agree on all turning points. The time path of the two series is similar until the 1959 steel strike. At this point the R_t series takes on higher peak and trough values. The computed regression result is

$$Wh_t = 12.682 + .917R_t - .297t \quad \bar{R}^2 = .9330.$$

(3.613) (.038) (.033)

Although the coefficient of time is significant, its sign indicates a downward bias in the Wharton Index. This result is due to the extremely high peaks which the R_t series reaches in the late fifties. As a result of the steel strike in 1959 and the associated production for inventories, it is felt that the Wh_t series is approximately correct, not subject to a bias drift, since the peak at 1959-2 was close to a full capacity peak on a priori grounds. The height of the R_t series in the 1958-1960 range is due to a computed downturn in the level of capacity. This resulted in forcing the R_t series higher than the Wh_t series at this peak compared to other capacity peaks. This computed downturn in the R_t series begins in 1958. This may be seen by looking at Table 2. Here we see the difference between R_t and Wh_t . This difference, until 1958, exhibits no clear trend; after 1958 there is a sharp increase in the difference. On the hypothesis that the 1959 peak was a capacity peak due to the steel strike and that the prediction of the R_t series after 1958 is false, we conclude that Primary Metals is not subject to a bias drift.

For Non-Electrical Machinery the time profile of the two series is quite similar. Both series agree on all major turning points except for the trough of the 1958 recession where there is one quarter difference. There is a bit of disagreement in the 1959-1960 range. By looking at Table 2 it is evident that there is no upward drift of the Wh_t series. Although there seems to be a systematic cycle, there is no evidence of a persistent upward drift in the Wh_t series. This is supported by the computed regression.

$$Wh_t = 9.217 + .906R_t - .141t \quad \bar{R}^2 = .8475,$$

(4.904) (.054) (.034)

TABLE 2—PERCENTAGE UTILIZATION OF CAPACITY BY INDUSTRIAL SECTOR
1948-1 TO 1960-4

(1) = R_t ; (2) = Wh_t ; (3) = $R_t - Wh_t$

| Quarter | Primary Metals | | | Nonelectrical Machinery | | | Electrical Machinery | | |

where the coefficient of time is of the wrong sign. We conclude that Non-Electrical Machinery is not subject to an upward drift.

By looking at the results for Electrical Machinery in Table 2 we see an example of the bias we are looking for. For Electrical Machinery from 1951-3 onward, there is a persistent downward drift in the difference $R_t - Wh_t$. This means that the Wharton series has been drifting upwards relative to the R_t series. Computing the appropriate regression for the period 1951-3 to 1960-4 we have

$$Wh_t = -7.337 + 1.022R_t + .234t \quad \bar{R}^2 = .9316.$$

(4.416) (.047) (.029)

The coefficient of time in this equation is significant and of the right sign. On this evidence we conclude in the case of Electrical Machinery that the Wh_t series is subject to drift since 1951-3.

In the case of Autos and Equipment the two series are extremely similar, with agreement at all turning points. By looking at Table 2 it is apparent that there is no systematic drift in the Wh_t series. The regression results yield

$$Wh_t = 20.214 + .684R_t - .193t \quad \bar{R}^2 = .8418.$$

(4.338) (.044) (.044)

Although the coefficient of time is significant, it is of the wrong sign. We conclude therefore that for Autos and Equipment the Wh_t series is subject to no bias drift.

For Stone, Clay and Glass the time path of the two series is very similar. Table 2 reveals that there is a persistent upward drift in the Wh_t series. This drift begins in 1950-3 and continues through 1960-4. The regression for the period 1950-3 to 1960-4 yields

$$Wh_t = 8.690 + .821R_t + .286t \quad \bar{R}^2 = .8330.$$

(5.965) (.057) (.033)

The coefficient of time is significant. For Stone, Clay and Glass, an element of bias has been found.

Food and Beverages reveal the most marked trend in the Wh_t series that we have noted thus far. The time profiles of the two series are extremely similar except for the persistent upward drift in the Wh_t series. This is revealed in Table 2, where there is a marked downward drift in the difference $R_t - Wh_t$. Computing the appropriate regression for the period 1948-1 to 1960-4 we have

$$Wh_t = 3.980 + .885R_t + .114t \quad \bar{R}^2 = .9628.$$

(4.447) (.045) (.004)

The coefficient of time is both significant and of the right sign. Food and Beverages is subject to drift.

For Textile Mill Products the time profile and agreement of turning points is remarkably similar. By looking at Table 2 a slight downward drift in the difference $R_t - Wh_t$ is detected since 1957-1. This suggests that there has been a slight upward drift in the Wh_t series since 1957. Computing the appropriate regression for the period 1957-1 to 1960-4, we have the result

$$Wh_t = .490 + .933R_t + .204t \quad \bar{R}^2 = .9847.$$

(3.019) (.033) (.041)

Paper and Allied Products show a marked upward drift in the Wh_t series from 1951 to 1960. This upward drift is clearly shown in Table 2. Apart from this drift, the time path of Wh_t is similar to that of the R_t series. Computing the regression for the period 1951-1 to 1960-4, we have

$$Wh_t = .176 + .916R_t + .298t \quad \bar{R}^2 = .9530.$$

(3.618) (.037) (.015)

Although Chemicals and Allied Products have a tendency to drift upwards from the period 1951 to 1958, this upward drift does not continue, as seen in Table 3. The regression for the entire period is,

$$Wh_t = 11.488 + .842R_t + .055t \quad \bar{R}^2 = .8312.$$

(5.278) (.054) (.018)

Although the coefficient of t is significant and has the right sign, we conclude that this series is not subject to bias drift. This result is based on the visual inspection of Table 2 rather than the regression result. We feel that the Table reveals the picture of a cycle rather than systematic drift. It is the long down swing in this cycle that yields the results of the regression, which we feel do not lead to correct judgment on trend drift.

For Rubber Products the time paths of the two series show agreement in all turning points as can be seen by inspection of Table 2. Table 2 reveals no systematic drift in the difference between the Wharton series and R_t . Computing the appropriate regression for the period 1948-1 to 1960-4, we find

$$Wh_t = 3.068 + .919R_t + .001t \quad \bar{R}^2 = .8549.$$

(4.919) (.053) (.024)

It is apparent from Table 2 that Public Utilities is subject to an upward drift. Table 2 suggests that this drift did not begin until 1950. Computing the appropriate regression for the period 1950-3 to 1960-4, we find

TABLE 3—THE ADJUSTMENT OF THE WHARTON AGGREGATE INDEX

| Quarter | Unadjusted Aggregate Wharton Index (1) | Eleven Sector Weighted Average, No Adjustment (2) | Eleven Sector Weighted Average, Six Adjusted (3) | (2)–(3) (4) | (1)–(4) (5) |

$$Wh_t = 7.307 + .869R_t + .199t \quad \bar{R}^2 = .9163.$$

$$(4.408) \quad (.043) \quad (.010)$$

We have examined the 11 industries under study and found six of these subject to a bias drift. Electrical Machinery has been drifting upward since 1951-3, Food and Beverages since 1948-1, Stone, Clay and Glass since 1950-3, Textile Mill Products since 1957-1, Paper and Allied Products since 1951-1, and Public Utilities since 1950-3. We assume that the remaining industrial sectors in our sample are not subject to drift.

Let us stop here to make some observations. We have found in all eleven industrial sectors studied, only one, Textile Mill Products, in which the bias drift conforms to previous suppositions about the nature and extent of the drift in the Aggregate Wharton Index. Only in Textile Mill Products do we find a significant upward drift in the Wharton Index commencing in the period after 1957. In one other industry, this drift begins as far back as 1948 and seems to originate for the most part in the period around 1951 to 1953. This, of course, is the Korean War period. Our results suggest that peaks in the years subsequent to the Korean War period have not been full capacity peaks. This result seems plausible; after 1951-1953 the economy's rate of unemployment has never fallen to the level reached in 1951-1953, even in the 1955-56 period.

X. The Adjustment of the Aggregate Index

In Table 3 we present the results of adjusting the Aggregate Wharton Index. Column one is the 30-sector weighted average (using F.R.B. weights) of the original Wharton Component Sector Indexes. This is the series from which we wish to eliminate the bias drift. Column two is an 11-sector weighted average of the unadjusted Wharton Indexes under study. Column three is the 11-sector weighted average of the Wharton Sector Indexes with zero adjustment in five and adjustment by the amount $-ct$ over the period during which the other six were found to be subject to a biased drift.

On inspecting column (4), which is the empirical counterpart of expression (17), it is apparent that by 1953 the Wharton Index is one point too high, and by 1960 this drift has increased to 4.02 points. In terms of the Aggregate Index, the 1953 peak is now at 95 compared to 96, the 1956 peak is now at 93 compared with 96 and the controversial 1960 peak is now at 89 compared with 93.

It is now clear that the Wharton bias may have been more the result of a long term buildup due to the fact that the 1956 and 1960 peaks were not as high as the 1951-1953 peak, rather than the result of some short-term phenomenon associated with the lack of a full cyclical recovery in

CHART 2. PER CENT UTILIZATION OF CAPACITY 1947-1965

1960. This phenomenon probably intensified the drift, but our results place the roots of the bias earlier in the 1950's.

XI. *Comparison of the Adjusted and Unadjusted Wharton Series with Another Measure of Capacity Utilization*

Peter Gajewski and Frank de Leeuw have constructed a utilization of capacity series designed for comparison with the manufacturing components of the F.R.B. industrial production index. For comparative purposes and contrast with the Wharton Index their series can be called the F.R.B. series. Their series is based on three indicators, the Commerce Department's series measuring manufacturing capital stock in 1954 dollars, the McGraw-Hill index of manufacturing capacity, and the December-January averages of the Federal Reserve output index for manufacturing divided by McGraw-Hill estimates of the end-of-year "rates of operation." Details of the procedure used and a discussion of the results are given in [6]. We will deal with a comparison of the Gajewski-de Leeuw series, denoted by I_t , with the adjusted and unadjusted Wharton series.

Charts 2 and 3 give a graphic display of the adjusted and unadjusted Wharton Index in comparison with the I_t series. In Charts 2 and 3,

CHART 3. PER CENT UTILIZATION OF CAPACITY 1947-1965

series 1 is the I_t Index. The unadjusted Wharton Index is found in Chart 2 as Series 2. The adjusted Wharton Index is Series 2 in Chart 3.

It is apparent by inspection of these two charts that the Wharton series, either adjusted or unadjusted, agrees in all turning points with the Gajewski-de Leeuw series. The cyclical pattern is extremely close. By comparing Chart 2 with Chart 3, the bias drift of the Wharton Index, in relation to the series I_t , is not only apparent, but also there is a clear indication that this drift has been reduced by our adjustment method. Another view of this is also given Chart 4. Here we see the difference $I_t - Wh_t^A$ and the difference $I_t - Wh_t$. The second difference is series 2. Series 2 has a clear negative trend in it. This suggests that the unad-

CHART 4. DRIFT IN THE DIFFERENCE 1948-1964

justed Wharton series has been drifting away from the I_t series. This is supported by the regression result

$$Wh_t - I_t = 2.6798 + .0559t \quad R^2 = .1583.$$

(.6375) (.0156)

The coefficient of t is positive and significant. The difference which results after the adjustment of the Wharton index shows no clear trend. This is supported either by inspection of Chart 4, Series 1, or the regression result

$$Wh_t^A - I_t = 3.445 - .0243t \quad \bar{R}^2 = .0254.$$

(.558) (.0149)

Here the coefficient of t is of the wrong sign and is barely significant suggesting that in relation to the series I_t the new Wharton Index is not subject to any bias drift.

XII. Conclusions

We feel compelled to stress in bare form and all together the main bold assumptions that we have made in this paper. It is a strong assumption to claim that capital and labor are utilized, by industry, at the same

rate; that our method of allocating labor force at full capacity among industries is correct; that firms minimize cost in a competitive factor market; that production follows the Cobb-Douglas law; and that our data properly measure the relevant economic concepts.

Some of these assumptions can be relaxed. Possibly other proxies for capital utilization can be tested, but it is unlikely that we shall actually be able to obtain direct estimates of capital utilization for most sectors. We do contemplate testing alternative laws of production—certainly the CES function. At the same time it will be possible to eliminate some of the effects of least squares bias in parameter estimation of production functions by estimating industry equations for cost minimization and production simultaneously. We can also introduce distributed lag adjustment processes that may improve our results generally, while enabling us to distinguish between short- and long-run capacity.

Data are continuously improving. In the future we should be able to make better industry estimates and to cover more industries.

In spite of these caveats and others that could be drawn, we feel that assumptions and procedures like ours must be followed if any results at all are to be obtained and that our results are plausible. We judge plausibility by the uses to which we have been able to put the measures. As general cyclical measures, our estimates have served well in investment and profit functions that are part of econometric models. It appears to be the case that our series give cyclical information in econometric equations that is not given by unemployment and other cyclically related series.

As to a more basic use of these series for gauging the long-run economic potential of the American economy, we are less definite that our series are the correct ones. Here we rely on arguments of intuitive plausibility. We feel that if the more extreme estimates that show utilization rates considerably below ours were to be raised to full capacity, the resulting targets would be mutually incompatible and highly inflationary.

STATE DIFFERENTIALS IN INCOME CONCENTRATION

By AHMAD AL-SAMARRIE AND HERMAN P. MILLER*

I. Introduction and Summary

The degree of income concentration varies considerably from state to state. The index of concentration for Mississippi, which has the most unequal distribution of income in the nation, is 50 per cent greater than for Utah, the state with the most equal distribution. Within this range, there are marked differences in income concentration among states which are systematically related to various factors that have a bearing on income distribution—stage of economic development; the degree of industrialization and urbanization; the industrial and occupational mix; resource endowments; the size, skill, age, sex, and race of the labor force; the rate of unemployment; etc. The primary purpose of this paper is to analyze the relationship between these economic variables and the degree of income concentration among states.

There is a long history of speculation among economists and statisticians about the reason for the skewness of the income curve which is often referred to as income inequality or concentration. The theories that have been developed to explain this phenomenon generally fall into two categories, "natural" and "institutional."¹ The former typically attempt to explain income distribution in terms of probability theory. In this sense they treat the income curve as a by-product in the play of natural forces like the distribution of ability and chance which are independent of the form of social or economic organization. These theorems have ranged from a view of the income curve as a joint probability distribution of biological traits transmitted by heredity [2] to the analysis of the curve in terms of a game of chance under certain specified conditions [7] [1] [21].

*The authors are, respectively, economist, Center for Economic Projections, National Planning Association, and chief, Population Division, Bureau of the Census. This paper is based on an unpublished doctoral dissertation by Ahmad Al-Samarrie, The George Washington University, February 1966. The underlying statistics are based in part on unpublished Census Bureau data developed jointly by the authors. To the many persons who gave advice and criticism we wish to express our appreciation. Special thanks are due to Professor Charles Todd Stewart, Jr., of The George Washington University, as well as to members of the National Planning Association staff, particularly Gerhard Colm, Sidney Sonenblum, and Joel Darmstadter.

¹One may add a third category which attributes the income differences among individuals to "consumer preferences" with respect to the willingness to assume risks [5] or to the choice of occupations [17].

The institutional approach attempts to explain income inequality in terms of the social and economic conditions which prevail at a given time and place. The unique stamp of these theories is the emphasis they place on institutional arrangements which they claim help to perpetuate inequality once it is established. An earlier generation of economists represented by Taussig [22, p. 246] and Pigou [20, pp. 650-51] placed great emphasis on the importance of inherited property as well as inherited capacity as causal factors of income inequality. Later empirical studies have supported their view that there is no "law" of income distribution. During the past 30 years major reductions of income inequality have taken place in the United States largely in response to changes in social and economic conditions [12] [8] [15, Ch. 8] [14].

Due to the lack of empirical data, little work has been done to explain why incomes are more concentrated in some areas than others or how and why the degree of concentration for specific localities has changed over time.² Information collected in the past two decennial censuses makes it possible to test various hypotheses regarding the relationship between the degree of income concentration and various socio-economic factors. In this paper an attempt is made to explain state-to-state variations in income concentration by means of a multiple regression analysis involving five variables: the functional distribution of income measured by the per cent of property income in the state personal income; the relative weight of agriculture in the state economy measured by the per cent of total income originating in agriculture; the quality of the labor force measured by median school years completed by adult persons; imperfections in the labor market arising from racial discrimination as measured by the per cent of non-white persons in the population of each state; and the extent of labor participation in the state economy as measured by the per cent of the civilian population employed. In 1949 and 1959 over five-sixths of the state-to-state variation in income concentration was accounted for by these five variables.

Among the variables tested, racial composition appears to be the most important factor in explaining inter-state variations in income

² Simon Kuznets [13] gave some attention to this subject. Based on the state data supplied by Seymour Goodman, Kuznets finds a clear association between the shares of the upper income groups and the level of per capita income—the shares are distinctly higher in low income than in high income states, reflecting similar differences in intersectoral inequality in participation income per worker. Almost the same conclusion emerges when he compares income inequality among the thirteen regions of Italy as well as among countries; in other words, the shares of the upper income groups are higher in less developed countries (regions) than in developed ones.

For international comparisons of income size distribution, see [11] [19].

concentration. Due perhaps to the relatively large outmigration of Negroes from the South, this factor was less important in 1959 than in 1949. The probable continuation of this migration trend along with the recent drive toward social and economic equality for nonwhites may mean a further reduction in the relative importance of racial composition as a factor in income inequality.

The per cent of income originating in agriculture accounted for a smaller proportion of the variance in income concentration from state to state in 1959 than in 1949. This reflects, *inter alia*, the marked decrease in the role of agriculture as a source of income and employment during the postwar years. A further reduction in the role of agriculture in future years may eventually eliminate this factor as an explanatory variable in income concentration.

With the continued dispersion of nonwhites throughout the country and the declining role of agriculture in the economy, these two variables should decline in importance as explanatory factors in income concentration. It is difficult to predict which of the remaining factors will increase in relative importance or whether new variables will enter the scene. It seems likely, however, that the level of education will increase in importance as an explanatory variable since it is now highly correlated with income concentration and seems to be increasing in importance as a determinant of income.

The analysis presented here is based on the 1950 and 1960 Census of Population reports for each of the 48 states and the District of Columbia which show the distribution of families by total money income before taxes. The measure of income inequality used is the Gini concentration ratio.³

Before proceeding with the analysis note should be made of several limitations of the data which require that the findings be interpreted with care. First, the income distribution in each state is based on a single year rather than the average of several years. Year-to-year fluctuations in the incomes of families are wide due to temporary or "transient" factors (unforeseen additions to or subtractions from income), which are assumed to cancel out over a long period of time, and to be uncorrelated with "permanent" income [9, pp. 155-57] [6, Ch. 3].

³ The Gini concentration ratio is a measure of income concentration that is derived from the Lorenz curve which is obtained by plotting the cumulative per cent of units (families) on the *X* axis against the cumulative per cent of aggregate income accounted for by these units on the *Y* axis. If all units had exactly the same incomes, the Lorenz curve would be represented by a diagonal drawn from the point of origin. Curves drawn to actual data invariably fall below this line and the greater the inequality in the distribution of income the greater the area between the diagonal line and the Lorenz curve. The Gini concentration ratio is defined as the proportion of the total area under the diagonal that is between the diagonal and the Lorenz curve. For further information and a diagrammatic illustration see [18].

The use of a single reference year for comparing income inequality may exaggerate the degree of inequality.⁴

Second, the data refer to the distribution of money income among families in each state. As such, they take no account of imputed (non-money) income components, and for differential price (cost-of-living) indexes among geographical units, both of which are pertinent to welfare considerations. There is reason to believe that the exclusion of these factors, particularly of differential cost-of-living indexes, tend, on the average, to exaggerate the income inequality of the agricultural and less urbanized states. Finally, the state income distribution data convey no information on the family size. Such information is relevant to interstate comparison of real income distribution because differences in income concentration among states may partly reflect variations in family size and composition.

II. *Interstate Differences in Income Concentration*

Table 1 shows a ranking of the states by the size of Gini's concentration ratio of pre-tax money income received by families in 1949 and 1959. The states are arranged in an "increasing" order of the inequality coefficient in 1949, i.e., the state with the smallest concentration ratio in 1949 is ranked first and the state with the highest ratio is ranked 49th.

Several inferences may be drawn from this table.

1. With few exceptions, the states with a high degree of industrialization and a high standard of living (as measured by per capita income) had a more equal distribution of income than the relatively low income states (the Southern and predominantly agricultural states). This fact is clearly shown in Table 2, where the states are divided into six groups based on the size of the concentration ratio. The mean (average) concentration ratio is computed for each group and compared with the corresponding average per capita personal income. Except for group II in 1949 and group III in 1959, the inverse relationship between the concentration ratio and the level of per capita personal income is continuous. In other words, per capita income decreases as we

⁴When comparing the income size distributions of different spatial units, the crucial issue is not so much whether there are undue variations in the incomes of various income groups as whether or not there are distinct interstate differences in the year-to-year fluctuations in the incomes of these groups. There are unfortunately no data that shed light on this question. One can conjecture, however, that the incomes of farmers, nonwhites, and older persons are subject to greater short-run variations than those of other income groups. Hence, the states which have more than proportionate shares of these groups (the Plains and the Southeastern States) may tend to have above average fluctuations in income, and thus a relatively exaggerated income inequality.

TABLE 1—GINI'S CONCENTRATION RATIO OF BEFORE-TAX MONEY INCOME RECEIVED
BY FAMILIES IN EACH STATE, 1949 AND 1959^a

| States | Concentration Ratio | | Rank ^b | |

Sources: Gini's concentration ratio is from Table 1. Personal income per capita is from U.S. Dept. of Commerce, Office of Business Economics, *Personal Income by States Since 1929*, Suppl. to *Surv. Cur. Bus.*, Washington, 1956, Table 2, p. 142; and *Surv. Cur. Bus.*, Aug. 1962, 42, Table 2, p. 11.

move from group I (the states with the lowest concentration ratio) to group VI (the states with the highest ratio).⁵

2. There was a decrease in the degree of income inequality for every state except West Virginia over the 1949-59 decade (intrastate decrease in the inequality coefficient). Part of the observed intrastate decline in the inequality coefficient during the 'fifties may be due to changes in the methods of collecting and processing the income data in the 1950 and 1960 Censuses.⁶

3. There was a considerable reranking of the states in the inequality coefficient between 1949 and 1959. Several of the agricultural states (notably Maine, New Hampshire, Oregon, Idaho, Montana, Colorado, and Kansas) moved to lower ranks (experienced greater than average decline in the concentration ratio) during this period. On the other hand, the states with a high degree of industrialization or urbanization—Michigan, New Jersey, Pennsylvania, Indiana, California, Illinois, and D.C.—moved to higher ranks among the states.⁷ With few excep-

⁵ In a study of the relationship between income distribution and taxation Thomas Hopkins also found an inverse correlation between state and income concentration and median income [10].

⁶ The ratio of decennial census money income to the corresponding national income estimated by the Department of Commerce was about 83 per cent in 1949 compared with about 95 per cent in 1959. The greater understatement of income in 1949 than in 1959 was largely due to the manner in which income was estimated. In the 1950 Population Census income information was obtained for the head of the family and for all other family members *as a group*. If income was reported for the head of the family, that amount was used as the total income for the family when no information was obtained for other family members. In the 1960 Census income was obtained separately for each member of the family. When income was not reported for a family member, imputations were made based on persons with the same characteristics—see [16].

⁷ The smaller than average decrease in the income inequality of Michigan and Pennsyl-

tions there was little change in the relative ranks of the southern states during the decade.

4. There was a moderate decrease in the "inter state" differences in the concentration ratio between 1949 and 1959. Table 3 summarizes the changes in the interstate dispersion of the Gini concentration ratio in 1949 and 1959. As can be seen, the standard deviation of state concentration ratio declined from about .043 in 1949 to .037 in 1959, or

TABLE 3—INTER STATE DISPERSION IN THE CONCENTRATION RATIO
OF INCOME RECEIVED BY FAMILIES, 1949 AND 1959

| Interstate Dispersion in the Concentration Ratio | Year | |
|---|------|------|
| | 1949 | 1959 |
| Mean ratio (\bar{x}) | .404 | .368 |
| Standard deviation (σ) | .043 | .037 |
| Coefficient of variation (v) | .106 | .102 |

about 13 per cent. The comparable decline in the coefficient of variation was nearly 5 per cent during the same period. These figures suggest that the states with relatively high concentration ratio in 1949 tended to show somewhat larger decreases in income inequality than the states with relatively low 1949 concentration ratio.

III. *Factors Associated with State Differentials in Income Concentration*

As previously noted, there are marked differences among states in various characteristics that are related to income concentration. States in which a large proportion of income is derived from property are more likely to have a greater concentration of income than those which are less dependent upon this type of income. States in which a large proportion of the population is uneducated or is engaged in low-paid employment are also likely to have a greater concentration of income than those in which education and high-paid employment are more widespread. In this study an attempt is made to examine the relationship between income concentration and various socio-economic characteristics by the use of multiple correlation-regression analysis.

In the analysis which follows, the relationship between the dependent variable (Y) and various independent variables ($X_1, X_2 \dots$) is defined by the equation:

$$Y = a + b_1X_1 + b_2X_2 \dots b_mX_m.$$

vania may have been due to the relatively high unemployment rates in 1959; the same phenomenon may also explain the slight decrease in the inequality of West Virginia's income distribution.

In this equation the dependent variable Y is the Gini concentration ratio for 1959; the independent variables $X_1 - X_{10}$ are described below; a is a constant, and $b_1, b_2 \dots b_m$ are the net regression coefficients.⁸

Y = Gini's concentration ratio of the size distribution of income received by families in each state in 1959.

X_1 = Property income as per cent of state personal income, 1959.

X_2 = Per employee labor income in agriculture as a ratio of per employee labor income in nonagricultural industries, 1959.

X_3 = Labor earnings in agriculture as per cent of total labor earnings from all industries, 1959.

X_4 = Per employee labor income in non-agricultural industries, adjusted for state industry structure, 1959.

X_5 = Per cent of labor force employed as clerical workers, sales workers, or craftsmen, foremen, and kindred workers in each state, 1960.

X_6 = Median school years completed by persons 25 years and over in each state, 1960.

X_7 = Percentage share of the age groups 35-64 years in the labor force of each state, 1960.

X_8 = Per cent of total families headed by females in each state, 1960.

X_9 = Per cent of nonwhite persons in the resident population of each state, 1960.

X_{10} = Civilian employment as a per cent of the civilian population of each state, 1960.

The ten independent variables outlined above were tested in a regression analysis with the state concentration ratio of family income size distribution in 1959. The results are summarized in Table 4.

1. The coefficient of multiple correlation with the ten factors on Y is .927, and the coefficient of determination is .860. This means that the ten so-called "independent" variables account for about 86 per cent of the state-to-state variation in the income inequality in 1959. The unexplained variation of roughly 14 per cent may be due to imperfect measurement, the use of an inappropriate regression equation (linear instead of curvilinear), and/or the exclusion of other relevant independent variables.

2. Measured by the t -values (i.e., the partial regression coefficients divided by their respective standard errors of estimate), only four variables are significantly associated with the dependent variable at the 99 and/or 95 per cent confidence level. These are: the per cent of total earnings originating in agriculture (X_3), the level of education (X_6), the per cent of population that is nonwhite (X_9), and the per cent of the civilian population that is employed (X_{10}). Measured by the "beta"

⁸ Two basic assumptions underlie the statistical analysis: (a) the forty-eight states and D.C. constitute the entire universe in 1959; and (b) the effect of different factors on the independent variables is assumed to be a linear relationship.

coefficients, X_9 is the most important factor in explaining the interstate variations in the concentration ratio (+.44), followed by X_3 (+.38), X_{10} (−.32), and X_6 (−.29).⁹ The other variable with a relatively high t -value is the per cent of property income in the state total personal income (X_1).

3. A close examination of the correlation matrix and the beta co-

efficients indicates that multicollinearity exists among the explanatory variables and that the condition of independence does not hold. Table 5, which presents the simple (zero-order) correlation coefficients among all the variables, shows that there is high correlation among many of the variables. For example, the states in which the per employee compensation in agriculture is relatively high compared to the per employee com-

⁹ The beta coefficients are obtained by multiplying the net regression coefficients by the ratios of the standard deviation of the different independent variables to the standard deviation of the dependent variable. By reducing the net regression coefficients to a common denominator, the beta values enable one to say which independent factor is the more important in explaining variations in the dependent variable. For example, a beta value of a +.44 for X_9 may be taken to mean that with an increase of one standard deviation in the per cent of families headed by nonwhite persons, the concentration ratio increases .44 of one standard deviation.

For a fuller treatment, see [3, pp. 773-74] [4].

pensation in nonagriculture (X_2) tend to be those in which the median years of schooling completed by adult persons are also high (X_6). Similarly, there is a negative association between the relative importance of agriculture in the state economy (X_3) and the proportion of persons in the skilled and white collar occupations (X_5).

Given the presence of multicollinearity, all the coefficients and the statistical test may be biased as a result. The standard practice in such a situation is to delete some of the weak explanatory variables, provided of course there are no serious theoretical objections to their exclusion. In this study, five variables were excluded from the analysis— X_2 , X_4 ,

X_5 , X_7 , and X_8 .¹⁰ The correlation of the remaining five factors with the dependent variable (the concentration ratio) is summarized in Table 6. Several inferences may be drawn from this table:

(a.) There was a very insignificant decrease in the coefficient of determination as a result of the exclusion of the given variables listed above—from .859 to .850. From a statistical point of view, this suggests that the factors related to the industrial affiliation of income earners (X_2 , X_4 , and X_5), and those related to the age and sex of the state labor force (X_7 , and X_8 , respectively), play a minor part in the explanation of state-to-state variation in the concentration of income.

(b.) The deletion of several variables produced a marked increase

¹⁰ The exclusion of these particular variables may be justified on two grounds: (1) they showed extremely low degree of correlation with the dependent variables, as evidenced by the relatively low t -value, partial correlation coefficients, or the beta values; and (2) they were significantly associated with the other independent variables, as indicated above.

in the relative importance of all the retained variables, particularly those relating to education (X_6) and to the proportion of nonwhite persons (X_9). This is clearly shown in the size of the partial correlation coefficients and, to a lesser extent, in the values of beta coefficients. The increase in the relative importance of X_6 was due primarily to the deletion of X_2 and X_5 , variables with which it has significant positive correlation. By the same token, the increase in the relative importance of X_9 was due primarily to the exclusion of X_8 , with which it has a positive association.

(c.) Compared to the initial situation, and using the beta coefficients as a frame of reference, the level of education (X_6) replaced the percentage share of the total earnings originating in agriculture (X_3) as the second most important factor in state-to-state variations in income inequality. There was no change in the relative ranks of race and per capita civilian employment. Although there was a moderate increase in the relative importance of property income (X_1), its association with

the state concentration ratio continued to be statistically insignificant.

The above analysis was repeated for 1949 using the variables previously described. The results, shown in Table 7, are basically similar to those obtained for 1959. The coefficient of multiple correlation for the five factors was .933 for 1949 as compared with .922 for the following decade. Several differences, however, may be noted in the relative importance of several of the explanatory variables.

1. The association between property income (X_1) and income concentration was positive in both years, but it was significant only in 1949. The decline in the importance of this variable is partly due to a

narrowing of state differentials in the proportion of property income in relation to total income during the 'fifties, reflecting, *inter alia*, the freemovement of productive factors and industries among geographic units.

2. Agriculture (X_3) was more important in the explanation of interstate variation in income inequality in 1949 than in 1959. The marked decrease in the share of agriculture in the national economy (a consequence of a rapid pace of mechanization in agriculture and a relatively inelastic demand for agricultural commodities) was perhaps the main contributing factor.

3. There was a significant inverse correlation between educational attainment (X_6) and the concentration ratio in both years. Education, however, was a more significant explanatory variable in 1959 than it was ten years earlier, as a result perhaps of the general rise in educational attainment.

4. The racial composition of the population was the single most important explanatory variable in both years, although this factor was less significant in 1959 than in 1949. The decrease in the importance of this variable is due largely to the out-migration of nonwhites from the South.

5. The per cent of the population that was employed (X_{10}) was a significant explanatory variable in both years, although it was of greater importance in 1949 than in 1959. This change is probably due to the observed tendency for states to become more similar in the proportion of the civilian population employed during the ten-year period.

A THEORY OF GROWTH WITH TECHNOLOGICAL CHANGE

By JAROSLAV VANEK*

A rather limiting feature of many of the formal growth models which have gained prominence—such as those of Professors Harrod [4], Domar [1], and Solow [6]—is that, to the extent that these models yield an equilibrium growth path, that growth path is one where per capita income either remains unchanged, or if it changes, it does so only because of an increasing efficiency of labor. In other words, if there is to be an increase in per capita income, this is so because in the production function a factor reflecting technical change (depending on time or otherwise) appears only as a term multiplying the labor input. The purpose of this paper is to explore a different growth theory—about which comparatively little is known¹—incorporating technical progress saving capital and labor in equal proportions (i.e., Hicks-neutral progress) and growth of productive resources.² At the same time, the theory presented here includes some of the other theories as special cases.

While what follows is certainly not an adequate description of the infinitely complex process of growth and development, nonetheless it is hoped that it may clarify some aggregative aspects of that process. In fact, as we will see in Section 4, the theory seems to be consistent with a number of key trends usually observed in growing economies, and can provide the rationale for several basic relationships among these trends.

I. *Definition of the Growth Model*

The growth theory we want to explore in this paper is exceedingly simple. It is a combination of the Solow growth model (with constant

* The author, professor of economics at Cornell University, expresses his grateful appreciation to his colleague Ta-Chung Liu for useful discussion of the subject treated in this paper. An outgrowth and further generalization of the theory presented in this article appeared in the *Economic Journal* of December 1966.

¹ For evidence of this see [3].

² At this point I should like to acknowledge an interesting contribution by C. E. Ferguson [2], which appeared after this paper was first submitted for publication. Starting from its definition, Ferguson derives the natural rate of growth of income for the Hicks-neutral growth situation. His result is the same as that obtained in this paper (relation [11]) for the "asymptotic" rate of growth of income. Ferguson also derives a number of other interesting expressions for the natural rate of growth which supplement the analysis of this paper.

Unfortunately, the relevance of Ferguson's natural rate for the general Hicks-neutral theory of growth is not made clear in his article. As we show later in this paper, in the general Hicks-neutral case (excluding that involving a Cobb-Douglas function, which is also Harrod-neutral), the actual rate of growth of income cannot be equal to the natural rate except possibly in isolated instances of infinitesimal duration. Under such conditions, the natural rate can be of interest to us only if we can learn from it something about the actual growth rates.

technology) [3] and the assumption of neutral technological progress, proceeding at a constant rate. The equations defining the model are as follows:

$$(1) \quad Y = Ae^{at}F(K, N)$$

where Y represents aggregate net output, A is a given constant, a is the constant rate of neutral technological progress, t is time measured from the base period, and K and N capital and labor inputs respectively.³ F is assumed to be unit-homogeneous, so that we can rewrite relation (1) as

$$(2) \quad Y = Ae^{at}Nf(K/N)$$

F is subject to a diminishing and nonnegative marginal rate of substitution, except for possible rates zero or infinity.⁴ Unless otherwise specified later in our discussion, saving (S) is taken to be a constant proportion s of national output, so that

$$(3) \quad S = sY$$

Finally, we make the customary assumption that saving equals investment, that is,

$$(4) \quad S = dK/dt$$

Dividing both sides of relation (2) by N so as to obtain per capita income, differentiating that equation with respect to time and dividing by per capita income we obtain a fundamental relation between the rates of growth, namely

$$(5) \quad y = a + \phi(k - n)$$

where y is the rate of growth of per capita income, k that of capital, and n that of population. The term ϕ can either be interpreted as the share of total income earned (under fully competitive conditions) by capital, or as the elasticity of per capita income with respect to a change in the capital-labor ratio, that is,

$$(6) \quad \phi = \frac{df/d(K/N)}{f/(K/N)}$$

In relation (5) n is a prescribed parameter, and is assumed constant in most of our subsequent discussion.

³ Throughout this paper we assume full employment and no change in the quality of labor, or in the population structure. Consequently, N can be understood interchangeably as labor-input or as total population. K is total capital stock, having the same physical nature as national product, and infinite durability.

⁴ That is, except for the case where for some capital-labor ratios the isoquants become parallel to an axis.

Once n is given, relations (2) through (4) together with prescribed initial levels of the three variables K_0 , N_0 , and $t=0$ allow us to trace the growth path for both income (or per capita income) and the capital stock. In the following section we examine these growth paths, primarily with reference to alternative initial conditions, while in the subsequent section our principal purpose is the analysis of the asymptotic properties of these growth paths, that is, the analysis of the limits imposed on the

FIGURE 1

rates of growth (if any) as the initial conditions recede to an increasingly distant past.

II. Description of the Growth Path

The assumption of linear homogeneity of the function F simplifies our task of describing alternative growth paths corresponding to the theory just defined. We do not have to consider all the possible combinations of initial endowments (at time zero) of capital K_0 and labor N_0 . It suffices to select arbitrarily one equal-product line, corresponding to $t=0$ and $Y=Y_0$, and consider as initial conditions only points on that contour, marked by $Y_0(t=0)$ in Figure 1. Whatever growth path then is shown for these initial conditions must also, *ceteris paribus*, pertain to any other initial conditions (K_0 and N_0), the scales of the two axes being adjusted by a common factor, in such a way as to make the alternative initial conditions fall on the isoquant as drawn in the diagram.

It will be observed that both the K -axis and the N -axis have a logarithmic scale. With a rate of growth of N constant, equal to n , paths along a 45 degree line, such as aa , indicate a constant rate of growth of

capital k , equal to n , while straight lines flatter than aa , such as bb , indicate a constant rate of growth of capital greater than n , and vice versa, for lines steeper than aa . Moreover, convexity towards the N -axis indicates acceleration of the rate of growth of the capital stock, and the opposite convexity deceleration of that rate.⁵

Now consider first the initial conditions II, and study the implications of a growth path aa , comparable to the equilibrium growth path in the Solow model. It will be seen that such a growth path, on the assumptions stated in the preceding section—especially, the assumption of a constant saving rate—is impossible. With constant and equal rates of growth of labor and capital, national income will grow at the rate of $n+a$ (recall that a is the autonomous rate of neutral technological improvement), and saving would have to grow at that same rate; but this contradicts the postulate that capital grows only at the rate $n(=k)$.

In fact, the growth path aa is possible only if s gradually declines over time at a negative rate. Specifically, s would have to be the following function of time:

$$(7) \quad s(t) = \frac{ne^{-at}K_0}{Af(K_0/N_0)N_0}$$

This situation, characterized by steady growth and proportionality of K and N , certainly is not a good description of what happens in the real world. Rather, it strongly suggests that with technological progress, in a world where the saving rate is relatively stable, capital and labor cannot grow at the same rate.

Nevertheless, the result summarized by equation (7) has a relevance for our analysis. Corresponding to initial conditions K_0 and N_0 at point II, there will be, from relation (7), a saving rate s_0

$$(7a) \quad s_0 = \frac{nK_0}{Af(K_0/N_0)N_0}$$

leading to the result that, at time zero, the growth path will have the slope of aa , that is, k will be equal to n . If that saving rate (s_0) is preserved, however, k must increase over time. Thus we obtain the "initial" segment of one growth path, marked II-II in Figure 1. As is indicated by its upward convexity, the rate of growth of capital must be accelerating in the early stages of expansion. On the other hand, it is self-evident that for constant saving rates greater than s_0 we will obtain initial growth paths such as II-II'' in the diagram. For saving rates falling short of s_0 , on the other hand, we have paths such as II-II'. If the two alternative saving rates are not too different from s_0 the convexity of

⁵ Note also that although the isoquant $Y_0(t=0)$ was drawn convex to the origin, this is not a necessary pattern in a double-logarithmic plane.

these two paths can be expected to be as indicated in Figure 1, that is, an acceleration of the rate of growth of capital is likely to take place in the neighborhood of point II. However, as we will see presently, this pattern can be reversed for high levels of saving rates.

Let us now briefly consider alternative "initial" labor and capital endowments. Suppose that the saving rate is now fixed at s_0 , so that we already have a part of a growth path, that corresponding to initial endowments marked II in the diagram. Altogether, four alternative cases must be distinguished, characterized by initial endowments I, II, III, and IV.

At point I the same amount of output is produced at time zero as at point II, the same saving rate s_0 pertains, but there is more capital and less labor. The increment in capital stock thus must be the same as at II; however, the rate of growth of capital must be smaller because the existing capital stock is greater. Consequently the slope of the expansion path at I is greater than at II (for path II-II), indicating that initially capital must be growing more slowly than labor (which is growing at a constant rate n). But as we will show in the following section, the rate of growth of k cannot remain indefinitely below that of labor. As indicated in the diagram, the rate of growth of capital will gradually increase, reaching at point A the rate of growth of labor ($k=n$). It cannot remain equal to n for the same reasons that the rate of capital $k=n$ could not have been preserved at point II. Rather it will keep increasing beyond point A , as is indicated by the convexity to the N -axis of the path passing through point I.

For successively lower initial capital-labor ratios (as we move our assumed starting point from I to IV) the initial rate of growth of capital (again with unchanged rate for labor n and the same savings rate s_0) must be successively higher. As will be noticed from the diagram, the slope of the expansion path at III is greater than that at IV. What makes the two situations III and IV different is the rate of acceleration. With initial condition III, capital initially grows faster than labor, and that rate gradually increases. With initial endowments K_0 and N_0 at point IV, the rate of growth of capital is even higher, but, as indicated by the curvature of the path, that rate is diminishing.

Relation (5) permits us now to derive from what has been shown for the rates of growth of capital and labor some corresponding results regarding the rate of growth of income. The initial rate of growth of income per capita (y) will be higher or lower than the rate of advance of technology (a) depending on whether the initial rate of growth of capital (k) is higher or lower than the rate of growth of labor. Accordingly, for initial condition I per capita income will be increasing at a rate inferior to a , for condition II at the same rate as technology, and for initial con-

ditions III and IV per capita income will advance faster than technology.

If in the initial stages the share of income earned by capital (ϕ) does not change significantly—on the limit, if it does not change at all, F being a Cobb-Douglas function—then what has been said above about acceleration of k must hold also for acceleration of y . Thus for initial condition I the rate of growth of per capita income (or, for that matter, aggregate income), while comparatively low, will be increasing, reaching the level α at point A in Figure 1, and keep increasing thereafter. At the other end of the spectrum, for initial condition IV, per capita income will grow at a high but diminishing rate.

FIGURE 2

III. *The Asymptotic Properties of the Growth Path*

The alternative patterns of growth illustrated in Figure 1 by growth paths corresponding to initial conditions I, II, III, and IV and a given saving rate s_0 strongly suggest that there ought to be some asymptotic rate of growth of capital (constant or variable over time)—such as that corresponding to the line bb or another contour, not necessarily a straight line—towards which any possible growth, corresponding to any initial conditions along Y_0 ($t=0$), would converge over time. Our main task in this section is to identify and to derive such a limiting path. We will do this in two distinct stages. First, we will show the dynamic equilibrium, or self-correcting, forces inherent in the present theory, leading to an asymptotic path. As we do so, many of the results stated in the preceding section will become clearer. Second, using simple mathematics, we will derive the asymptotic growth rates and some related results for the whole class of linear homogeneous functions F , as well as for the specific case of functions F of the Cobb-Douglas type.

Consider Figure 2. The contour marked $Y(0)/K$ represents the

average product of capital, corresponding to the production function at time $t=0$, expressed as a function of the capital-labor ratio, K/N . The lower contour is obtained by multiplying the contour just identified by the saving rate s_0 . As indicated in the diagram, besides being saving per unit of capital, it also is the rate of growth of capital in period zero. The horizontal line mn indicates the rate of growth of labor, assumed constant.

As time advances starting from $t=0$, the two downward sloping contours (i.e., the average product of capital, and the schedule indicating the rate of growth of capital) keep shifting upwards at the constant rate a (say, two per cent of the vertical distances per annum). The mn line, on the other hand, remains unaltered. Simultaneously, as time advances, the capital-labor ratio keeps changing at the rate $k-n$. For example, with initial conditions corresponding to point d , the capital-labor ratio must be advancing at the rate $(cd-cb)$.

The growth process thus can be characterized as a composite continuous movement (1) along the k -schedule, and (2) with the k -schedule. The horizontal component of the first movement is equal to $k-n$, while the vertical movement of the k -schedule proceeds at a constant rate (of technological progress) a .

Consider first initial conditions corresponding to point D , reflecting the situation described by II in Figure 1. In that case, at the particular initial instant of time, the rates of growth of capital and labor are equal. But this cannot last, because, as time goes on, the k -schedule moves upwards, and a positive $k-n$ gap is opened.

Suppose now that the initial capital-labor ratio is higher than that just examined, say, corresponding to point d' . The $k-n$ gap now is negative and the capital-labor ratio must decline. At the same time the k -schedule keeps shifting upwards. Both changes cooperate in closing the $k-n$ gap, and thus, in reversing the movement along the horizontal axis from leftwards to rightwards. That reversal will take place when the traveling points such as d' and b' meet, somewhere to the right of D . Such a point corresponds to point A in Figure 1, and the whole situation corresponds to the path starting from I in that Figure. It is also easy to see now that the rate of growth of capital must be increasing, not only up to but beyond the time when the direction of movement of the capital-labor ratio is reversed.

Consider now initial conditions reflected by some point between d and D , that is, for a capital-labor ratio falling within the range III (comparable to initial conditions III in Figure 1). In this region the $k-n$ gap, while positive, is relatively small, so that the movement to the right along the horizontal axis is comparatively slow. But the k -schedule keeps shifting up at the constant rate a , and this keeps opening

the $k-n$ gap further so that the rightward movement along the horizontal axis is accelerated.

For initial points to the left of d , the situation is different. With a significant $k-n$ gap, the capital-labor ratio moves to the right at a fast rate, but because the rate of vertical movement of the k -schedule in this region (corresponding to IV in Figure 1) is still the constant a —the same as for region III—the rate of increase of the capital-labor ratio, and hence of capital, is declining.

It is evident that at some point the forces causing a deceleration in the rate of growth of capital in region IV and the forces causing an acceleration in region II just balance out, and there will no longer be any tendency, for a while at least, for k to increase or decline further. It is clear from our discussion that starting from any initial conditions the system will naturally converge to such a state. Actually, even at time zero, there must be a point on the k -schedule fulfilling these conditions; namely, that k , while greater than n , will tend initially neither to increase or to decline. Such a point is illustrated by point d in Figure 2. The locus of points, corresponding to points such as d for all possible time periods, traced in the capital-labor plane (see Figure 1), is then our "asymptotic path." It will be clear from the construction of Figure 2 that to each saving rate will correspond another asymptotic path. The rates of growth of capital and per capita income corresponding to that path we may refer to as asymptotic rates, and use for them the notation \bar{k} and \bar{y} . We now turn to the derivation of these asymptotic rates.

Using relation (2), the definition of the rate of growth of capital is

$$(8) \quad \dot{k} (= s_0 Y/K) = s_0 A e^{at} (N/K) f(K/N)$$

An extreme value of k (maximum or minimum), corresponding to a limiting point such as d in Figure 2, implies $dk/dt=0$, that is,

$$(9) \quad 0 = s_0 A e^{at} (N/K) [a + (n - k) + (k - n)\phi] f(K/N)$$

Dividing both sides of the equation by the product of terms outside of the square bracket and solving for k , we obtain what we have previously referred to as the asymptotic rate of growth of capital, that is,

$$(10) \quad \bar{k} = n + a/(1 - \phi)$$

Using relation (5) we obtain the asymptotic rate of growth of per capita income:

$$(11) \quad \bar{y} = a/(1 - \phi)$$

Realizing that the rate of growth of (K/N) is equal to $(k-n)$, it follows that both the asymptotic rates of growth of per capita income and per capita capital stock are identical.

As could have been expected, if the function f contains a region where the marginal productivity of capital becomes zero—that is, $\phi=0$ —any actual growth path must lead eventually to such a region (note that capital cannot grow indefinitely at a rate lower than or equal to n), and income per capita eventually will grow at a rate of technological progress a . A less self-evident result is that in the case where the marginal productivity of labor is zero, i.e., $\phi=1$, any actual growth path must eventually lead to an infinitely high rate of growth of per capita income and of the capital stock. Both outcomes are the immediate consequence of the convergence of actual towards asymptotic rates explained above.

One or the other of these extreme results must also be reached asymptotically if F is a “constant-elasticity-of-substitution function” excepting the Cobb-Douglas function, depending on whether the elasticity of substitution for capital is greater or lower than unity. In the former case the rate of growth of per capita income will asymptotically approach the rate of technological change a , and in the latter it will approach infinity.

The Cobb-Douglas function characterized by a unit elasticity of substitution and constant income shares ($\phi=\text{constant}$) yields the neatest results. We will elaborate on that case a little to clarify further the implications of our growth theory. First, it will be observed that, with constant income shares, both asymptotic rates \bar{k} and \bar{y} will be constant, not changing with the capital-labor ratio. Observing then that \bar{k} must be larger than n , we obtain an asymptotic growth path such as that illustrated by the line bb in Figure 1. The slope of that line is given by \bar{k} and n , and thus the path can be fully determined once we know one of its points. The intersection of bb with Y_0 ($t=0$) is such a point; it can be established as follows.

For a Cobb-Douglas function, f becomes $(K/N)^\phi$. Substituting that expression into relation (8) and writing (in that equation) $N_0 e^{nt}$ for N and $K_0 e^{kt}$ for K , and moreover, substituting for k the asymptotic rate \bar{k} as given in relation (10), we get

$$(12) \quad \bar{k} = n + a/(1 - \phi) = s_0 A (N_0/K_0)^{(1-\phi)} e^{t[a - s_0 + n(1-\phi) - n(1-\phi)]}$$

The exponent of e being zero, \bar{k} effectively is independent of time, and the asymptotic growth path consistent with that rate (i.e., $n + a/(1 - \phi)$), with a prescribed s_0 and A , is that for (N_0/K_0) satisfying relation (12). It is immediately apparent that changes in s_0 will not affect the slope of the asymptotic line such as bb in Figure 1, but will change its position. For higher saving rates we will have paths closer to the K -axis. If the initial K_0 and N_0 are such as to satisfy relation (12), the economy will expand indefinitely at constant rates $n + a/(1 - \phi)$, n , and $a/(1 - \phi)$ for capital, labor, and per capita income respectively. With any other initial

conditions the actual growth path will converge indefinitely towards that asymptote, as indicated for paths I, II, III, and IV in Figure 1.

For all other functions F of the class considered here ϕ will be changing with the capital-labor ratio and thus, with $a \neq 0$, the asymptotic path will not be a straight line (that is, \bar{k} and \bar{y} will not be constant). However, it still is defined (recall our discussion of points such as d earlier in this section), and can be expected to reach a linear form (such as bb) as time goes on, for very high capital-labor ratios. This is so because it is reasonable to expect that, for such ratios, ϕ will reach some stable value within the range (zero to one). But even if ϕ kept wiggling indefinitely (say, along a sine-curve) as K/N goes to infinity, relations (10) and (11) would still give us the corresponding values for the asymptotic rates of growth of capital and per capita income.

Of course, when $a=0$, that is, when technological progress is absent, the asymptotic path must be linear for any function F . This is the situation studied by Solow in his paper referred to in the introduction, and the corresponding rates are, from relations (10) and (11), $\bar{k}=n$ and $\bar{y}=0$.

When \bar{k} and \bar{y} are not constant, the problem of asymptotic convergence becomes a good deal more complex. Actually, as we will see presently, in such situations the term "asymptotic" must be given a broader interpretation than that implicit either in the Solow model or in the case of a Cobb-Douglas function discussed above. In what follows, we will concentrate primarily on the analysis of k and \bar{k} , recalling that corresponding results for y and \bar{y} can be derived from relation (5).

Suppose that \bar{k} is not constant (as it was for the Cobb-Douglas function) but rather a function of the capital-labor ratio, that is, $\bar{k} = \bar{k}(K/N)$. Three typical patterns for \bar{k} must now be envisaged; they are illustrated by the solid lines in Figures 3a, b, and c. All these figures reflect the same space as that of Figure 2, (K/N) being measured along the horizontal, and various rates of growth along the vertical axis.

The \bar{k} -contours divide the plane of these figures into two regions. Any actually realized rates (k) above these contours must be declining, and any actually realized rates below these contours must be increasing. This is what we have previously termed the "broader interpretation" of the asymptotic rates. Note that this interpretation does not require the decline in the difference between k and \bar{k} to an arbitrarily low level as time and K/N goes to infinity. It will also be noted that the contours \bar{k} , for functions F considered here, can never fall below the line corresponding to the rate $n+a$. This is immediately apparent from relation (10). Moreover, it follows that with \bar{k} always remaining at or above $n+a$, the actual rate of growth of capital k cannot indefinitely remain below $n+a$.

Six alternative actual paths for k , corresponding to initial conditions I through VI, reflect the asymptotic properties (broadly interpreted)

FIGURE 3a

FIGURE 3b

FIGURE 3c

specified above. For example, corresponding to initial conditions I, we find a continuous decline of k with continuously declining \bar{k} as time and K/N increase. As is illustrated, for example, by the path corresponding to initial conditions V, with \bar{k} not constant, k and \bar{k} can be equal (the k - and \bar{k} -paths will intersect) only when k passes through a maximum or a minimum. This is an immediate consequence of the fact that above \bar{k} , k must be declining, and below \bar{k} , k must be growing, as K/N (necessarily) increases.

From the fact that for $k = \bar{k}$ the actual rate k must be stationary, it follows that, whenever \bar{k} increases or declines over time, and k moves in the same direction as \bar{k} , the two rates cannot ever be equal. With \bar{k} increasing or declining over a prolonged period, such as in Figures 3a and 3b, k actually will converge to an asymptote (customarily, or

"narrowly" interpreted), which must remain at a certain minimum distance from \bar{k} . That minimum distance will vary, among other things, with the slope of the \bar{k} -contour.

In the real world, where ϕ (the competitive share of capital) generally changes only very slowly, if at all, and never comes too close to one, the slope of \bar{k} could be only very small. Under such conditions, it could be expected that k would come very near \bar{k} after a prolonged period of adjustment.

An interesting property of the \bar{k} -path is that that path, together with the prescribed rates of technological progress a and of population growth n , makes it possible to construct rather easily an actual k -path (such as the six broken lines in Figures 3a, b and c) once the initial point (such as points I through VI in Figures 3a, b and c) reflecting the initial capital-labor ratio and the initial rate of growth of capital is given. And thus, once the initial level of output or the initial supply of one of the two productive factors is also specified, the entire growth pattern can be fully described.

Moreover, knowledge of the \bar{k} -path and of a makes it possible in some situations—to be specified presently—to derive the true, or narrowly interpreted asymptote of k .

To show these results, let us return to equation (9). Its righthand side, as will be recalled, is the rate of change, with respect to time, of the rate of growth of the capital stock. Thus, making use of relation (8), we can write

$$(13) \quad \dot{k} = dk/dt = k[a - (k - n)(1 - \phi)].$$

Whence, dividing by k and making use of relation (10), we get

$$(14) \quad \dot{k}/k = a \left(1 - \frac{k - n}{\bar{k} - n} \right).$$

or, alternatively,

$$(15) \quad \dot{k}/k = a \frac{\bar{k} - k}{\bar{k} - n}.$$

In words, the rate of acceleration of capital, \dot{k}/k , is the rate of technical change, a , times the ratio of the excess of the asymptotic rate \bar{k} over the actual rate of growth of capital, and the asymptotic rate of growth of capital per laborer ($\bar{k} - n$). Thus, when k equals n , as at point D in Figure 2, \dot{k}/k is exactly equal to a ; and, as required by the definition of \bar{k} , when k equals \bar{k} , \dot{k}/k is zero. Moreover, as indicated by the broken contours in Figures 3a, b and c, above \bar{k} k must be declining, and below \bar{k} k must be increasing.

The convergence of an actual path of k towards a true (narrowly interpreted) asymptote—to be denoted k' —can now be further illustrated. Suppose that \bar{k} grows at the (positive) rate b , so that we can write

$$(16) \quad \bar{k} = \bar{k}_0 e^{bt}.$$

As both \bar{k} and k become very large after a prolonged period, the right-hand side of relation (15) will be approaching $a(1 - k/\bar{k})$, and a path

$$(17) \quad k' = k'_0 e^{bt}$$

where k'_0 is determined from

$$(18) \quad b = a \left(1 - \frac{k'_0 e^{bt}}{\bar{k}_0 e^{bt}} \right)$$

must then come arbitrarily near to the actual path k , after a sufficiently long period. This is so because whenever the actual k is smaller (greater) than $k'_0 e^{bt}$ in a given period the actual rate \dot{k}/k must be greater (smaller) than b .

Using relation (18) we get the value of k'_0 , namely

$$(19) \quad k'_0 = \bar{k}_0 \left(1 - \frac{b}{a} \right).$$

Thus in the special case where \bar{k} grows at a constant positive rate b over time, the true asymptote k' will be a line remaining at a distance $\bar{k}(b/a)$ below \bar{k} .

As was noted already, \bar{k} can never fall below the level $n+a$. Consequently, any continuing decline of \bar{k} must eventually lead to that level, and, as pointed out previously, capital will then grow at a rate k approaching the constant rate $n+a$. Such a situation is illustrated by Figure 3a.

Let us now consider briefly the actual rate of growth of per capita income y , and its relation to the asymptotic rates. We have already pointed out that y is given through relation (5) once a , k , n , and ϕ are known; consequently, once the variation of k is established, that of y can readily be obtained.

However, there is a more direct relationship between the rate of growth of per capita income and the actual and asymptotic rates of growth of capital just studied. This relationship, to which we now turn, will be useful to us in the following section. Using relation (5), the difference between the actual per capita rates of growth of income and capital is

$$(20) \quad y - (k - n) = a - (k - n)(1 - \phi).$$

As is apparent from relation (13), the righthand side of relation (20) is nothing but the rate of acceleration (the rate of growth of the rate of growth) of the capital stock, \dot{k}/k . Thus we can write

$$(21) \quad y = (k - n) + \dot{k}/k$$

and, using relation (15),

$$(22) \quad y = (k - n) + a \frac{\bar{k} - k}{\bar{k} - n}.$$

The already established fact that $\bar{y} = \bar{k} - n$ is now immediately apparent. Moreover, relation (22) tells us that whenever the actual rate of growth of capital falls short of the asymptotic rate, per capita income must grow faster than per capita capital stock, and vice versa for $k > \bar{k}$. More exactly, the difference between the (actual) per capita rates of growth of income and capital is equal to the difference between \bar{k} and k , that difference being measured in units of $(\bar{k} - n)/a$.

IV. *Some Reflections on the Theory in the Light of Observed Growth Patterns*

Before concluding our analysis, it may be of interest to confront the theory explored in the foregoing sections with growth patterns observable in the real world. Clearly, we cannot bring together all empirical data which would be relevant; instead, we limit ourselves here to a rather randomly selected and not always overly rigorous set of observations. Also, it must be kept in mind that any such observations can never provide a proof of the validity of the theory. They can only, to the extent that patterns consistent with the theory are observed, strengthen the hypothesis that the theory is an adequate one, and, to the extent that inconsistent patterns are observed, refute the theory's validity, or, more constructively, suggest possible improvements or alterations.

First, unlike a number of existing theories of growth, the theory presented here yields an explanation of a lasting state of expansion where capital must grow faster than population (or the labor force) and where, as a consequence (see relation [5]), income per capita must grow. Such trends are generally encountered in advanced economies.

Moreover, for economies in early stages of development, with a low capital-labor ratio, and a significant increase in the saving rate, we often observe a very high rate of growth of income accompanied by a gradual deceleration of that rate. Such a situation is illustrated by a growth path corresponding to initial conditions IV in Figure 1.

We can now turn to the U.S. economy, for which probably the most comprehensive statistics are available and where, during a prolonged period of growth characterized by a comparatively stable saving rate,

the dynamic forces studied in the earlier sections could have become satisfactorily operative. We can organize our remarks under two distinct headings: 1. Equilibrium dynamics, and 2. Disequilibrium dynamics.

1. Suppose that our theory is applicable, and that during a certain period of expansion in the American economy the rate of technological advance was reasonably stable; suppose, moreover, that during that period the growth path remained at or near the asymptotic growth path. If these conditions are fulfilled, then an estimate of the rate of growth of technology, a , can be obtained from relation (11) as $a = \gamma(1 - \phi)$.

Now we know from our previous discussion that when the actual growth rate of income is equal to the asymptotic rate, then the rates of growth of per capita income and capital must be equal. (Note that the asymptotic rates of growth of per capita income and capital are equal, and that, by definition, equality of actual and asymptotic rates of growth of income implies equality of actual and asymptotic rates of growth of capital.) Such conditions are quite satisfactorily fulfilled for the American economy, using Solow's tabulations, [7, p. 315] for the period 1909–1930, when income per man-hour grew at an average rate of $\gamma = 0.016$, only slightly less fast than employed capital per man-hour. Using 0.28⁶ as a reasonable estimate of the net competitive share of capital ϕ for the period, instead of Solow's approximately 0.34⁷ reckoned on a gross basis, we obtain $a = 0.0115$. Solow's estimate for this [the corresponding] period is $a = 0.0009$, but it is obtained using gross rather than net capital income share, and would have come to just about our 1.15 per cent if net rather than gross income share were used in Solow's calculation.⁸

A more recent and presumably more reliable set of data fitting our theory is found in Kendrick's study of productivity trends in the United States [5]. As with Solow's period 1909–1930, the portions of Kendrick's series covering the period 1889–1919 reveal only a small difference between the rates of growth of capital and income per unit of labor input [5, pp. 327–30], the latter rate being 0.016. The average income share of capital for the period, extrapolating Kendrick's data [5, p. 121], is about 29.5 per cent, there being an insignificant (about one-tenth of a percentage point per annum) decline in that share over

⁶ As we will see presently from John W. Kendrick [5], this share seems to be a good approximation of the average net share for the period.

⁷ There is no discernible trend in the yearly data on which this average is based, and consequently it can be postulated that the asymptotic rates for the period—of course, assuming a constant a —are invariant.

⁸ Actually, the question can be asked whether Solow's use of the gross share (of course, forced on him for lack of other data) did not lead to a set of downward biased estimates, and whether the figure 0.0115 obtained here is not closer to the true growth parameter for the period.

the thirty-year period. Using these estimates of γ and ϕ , we obtain an estimate of $a=0.011$. Kendrick's calculations of the rate of growth of total factor productivity—conceptually comparable to our parameter a —lead to an estimate of 0.010 for the same period [5, p. 67].

2. Now if calculations similar to those just explained are performed for the more recent portions of Solow's and Kendrick's series—covering 1930–1949 and 1919–1953 respectively—estimates of a significantly below those of the two authors are obtained using our method. But this is, as we will see, perfectly consistent with the theory of growth presented here. Because the arguments for the two cases are similar, and because Kendrick's data are more complete and probably more reliable, we will restrict ourselves in what follows only to the analysis of Kendrick's statistics.

Kendrick's estimate of the rate of growth of total factor productivity for 1919–1953 is 0.021 or 0.022, depending on the method used in fitting a regression [5, p. 67]. In either case, his calculations show that the rate of technological progress has more than doubled between the first and second periods. Using our "equilibrium" method of estimation of a for the second period (i.e., $a=\gamma(1-\phi)$), we obtain $a=1.5$.

While Kendrick's estimate of the average share of capital income for the first period (1889–1919) is somewhere near 30 per cent, that for the second is somewhere near 24 per cent, or even lower; moreover, during the second period a marked decline is observable in the share (about three-tenths of a percentage point per annum). Remembering that even for the first period there was some decline in our estimator of ϕ , the asymptotic paths of \bar{k} corresponding to Kendrick's information can be characterized, using concepts developed in this paper, in the following way: Both paths of \bar{k} for the first and second periods are declining, comparable to the solid line in Figure 3a, but the path for the second period is about twice as high as that for the first (see relation [10]) because of the more than doubling of a and some (offsetting) decline in ϕ . Now if during and toward the end of the first period the actual growth path were near the asymptotic path (as we have argued in the introduction), and a comparatively abrupt upward shift in the asymptotic path of \bar{k} took place in the second period, a dynamic disequilibrium situation must have arisen wherein the actual path of k suddenly found itself considerably below the new asymptotic path. The period of transition (around 1920) can thus be characterized by the situation described by point II in Figure 3a.

From relation (22) it follows that in such a situation the actual rate of growth of income must be considerably above the actual rate of growth of capital. Such were, as is well known, the historical trends; the real product-capital ratio, according to Kendrick [5, pp. 327–330], increased by about 50 per cent over the second period (1919–1953). More-

over, the rate of growth of real income (product) per unit of labor input should have increased in the second period; this is easily established from Kendrick's chart [5, p. 66].

Finally, as indicated by the pattern described in Figure 3a by initial conditions II and the segment of the k -path immediately to the right of point II, the actual rates of growth of capital and income should have been gradually approaching the asymptotic rates in the course of the second period. If such a "rapprochement" were fully effected, the actual rates of growth of capital and income should have come again to equality for rates of growth of capital k in the vicinity of the asymptotic rate \bar{k} . Such a situation is in fact observable from Kendrick's data [5, p. 330] for the period following World War II.

But if the asymptote were again at least approximately approached in the most recent segment of the second period, then our "equilibrium" formula for estimating a ($a = y(1 - \phi)$) should again be applicable. Because the period is very short, and because there is a good deal of year-to-year variation, the corresponding estimate may not be very reliable. However, using Kendrick's estimates of (national) output per unit of labor input for the period 1947-1957, we get an estimate of $y = 0.026$. Coupling this with the average share of income of capital for the period of about 21 per cent, also taken from Kendrick's work [5, p. 121], we obtain exactly Kendrick's estimate for the second period, namely $a = 0.021$.

The strong downward bias of the estimate of a ($= 1.5$ per cent) resulting from the application of the "equilibrium" formula to the entire period 1919-1953 can now be easily explained. Because through most if not all of the second period k was below \bar{k} , as we have argued above, y must also have been less than \bar{y} ; but it was y that was used in obtaining the estimate $a = 0.015$. Were considerably higher values of \bar{y} used *correctly* in the "equilibrium" formula, an estimate much closer to Kendrick's 0.021 would have been obtained.

ON THE THEORY OF OPTIMUM EXTERNALITY

By F. TRENERY DOLBEAR, JR.*

Modern welfare economics has established the Pareto optimal properties of a competitive economic system which satisfies such customary requirements as convexity and the absence of externalities. A frequent problem of the welfare economist is: Given all of the *other* requirements for Pareto optimality, how can a situation characterized by the presence of an externality be altered so as to produce a Pareto optimum? In the discussion which follows we will, for convenience, presume an external diseconomy.

Most of the formal analysis on externalities has been concerned with relationships between firms;¹ in this paper the actors will be consumers. As a result our analysis will be derived from the theory of consumer behavior instead of the theory of the firm. Although space limitations prohibit a detailed comparison, some of the results will be sensitive to this distinction since the usual welfare objective of maximizing joint profits subject to price parameters cannot be carried over to consumers without interpersonal comparisons of utility.

The occurrence of an external diseconomy will, in general, lead to a discrepancy between marginal *social* net benefit and cost. It is often presumed that a single device such as a per unit tax or individual negotiations can be used to correct the inequality.² While one of these prescriptions may improve the efficiency of the economic system, it will be argued here that it need not, in general, result in a Pareto optimum even if used in the best way.

It is sometimes presumed that the parcelling of legal responsibility³

¹ For example, Davis and Whinston [4], Wellisz [16], Coase [2], Kneese [8], and Kamien, Schwartz and Dolbear [7].

² For some qualifications on the use of these devices see Coase [2], Buchanan and Stubblebine [1], Davis and Whinston [4, 5], Turvey [15], Wellisz [16], and Mishan [9].

³ It is not for an economist *qua* economist to assess legal responsibility for an externality. For example, suppose my neighbor has a coal furnace and I find the smoke from his chimney noxious. Most people (I know) would hold my neighbor responsible. Now, suppose my neighbor paints his house gray and I find gray a depressing color. Here most people would hesitate to blame my neighbor. Determination of responsibility for externalities seems to have more to do with private property rights than with economics—which makes it a matter for the courts or for a legislative body. Of course, the law might permit a certain amount of externality as the "status quo" (starting point); i.e., the law does not always stipulate a polar solution (see Davis

does not affect the solution that market-bargaining forces will produce in the presence of an externality.⁴ But we will show that where consumers are involved the amount of externality may be very much affected by legal matters.⁵ Since changes in legal responsibility will alter the distribution of real income, there may be an "income effect" which will be of some consequence vis-à-vis the amount of externality. Of course, given a specific assessment of legal responsibility there may be a further income effect if the parties involved have opportunities to negotiate along the contract curve.

To illustrate these points we will resort to a highly simplified and somewhat artificial example involving two individuals X and Y . (The results will be extended to a world with m X -type individuals and n Y -type individuals in Section V .) It is hoped that the example will illustrate some difficulties which have been encountered in the analysis of real world problems.

I. A *Triangular Edgeworth Box*

Presume two consumers, X and Y , who form a "community" in a large economic society. Both have simple consumption patterns. X lives by bread and heat; Y lives by bread alone. However, Y is so situated that he receives air pollution in the form of smoke produced by X 's fire. We presume Y cannot—or at least that it is uneconomical to—move to a location which would escape X 's smoke output. Further, X can only reduce the amount of smoke by decreasing heat.⁶

Our analysis will use indifference curves and budget lines. First, X has indifference curves for bread and heat which meet the usual requirements in the theory of consumer choice (Figure 1). On the other hand, Y has indifference curves for varying quantities of bread and smoke. They are also shown in Figure 1 and have the standard characteristic that the more bread and smoke Y has, the more bread he will trade for a given amount of smoke abatement. By construction we establish Y 's smoke scale so that it corresponds precisely with X 's heat scale.⁷ For conveni-

and Whinston [5]). Pigou [10], who is most frequently footnoted as the precursor of externality discussions, did not explicitly recognize this indeterminacy. To my knowledge the point was articulated first by Coase [2].

⁴ Coase [2] and Kneese [8] obtain this result for externalities among firms.

⁵ This point has been made (but not demonstrated) by Buchanan and Stubblebine [1].

⁶ Buchanan and Stubblebine [1] analyze a comparable problem (for a fence and a numeraire good). Their construction, using "marginal evaluation curves," is similar in content to the one presented here; however, income effects cannot be analyzed directly because costs (for the fence) are handled by modification of the marginal evaluation curves. Also their example is restricted to two individuals.

⁷ We have no conventional measure for units of smoke (nor of heat). For our purposes it is sufficient that units of smoke be a multiplicative function of units of heat.

ence in developing the argument below, Y 's bread axis reads from top to bottom.

Given an X - Y community income endowment, the opportunity locus or budget line is shown as FF in Figure 2. The intercepts of budget line FF give the maximum amounts of bread or heat (smoke) which the community can purchase, and the slope of FF represents the ratio at which

FIGURE 1

heat can be traded for bread. This price ratio between heat and bread is presumed to reflect society's opportunity cost in terms of bread of producing one unit more of heat (the marginal rate of transformation). We presume that variation in the amounts of bread and heat purchased by X and Y will not affect this rate of transformation.

The triangle formed in Figure 2 by the two axes and budget line FF may be thought of as a type of Edgeworth box. The standard two-commodity, two-individual, rectangular Edgeworth box has several distinctive features. Any point in the box unambiguously defines quan-

ties of each commodity for both individuals. Thus indifference curves for each individual can be transcribed into the box. The tangencies of these indifference curves provide the locus of efficient allocations, in the Pareto sense, between the two individuals (the contract curve). However, if the total quantities of the two commodities are variable, according to the marginal rate of transformation, the welfare implications of the contract curve do not hold.

In this example, where there is a one-to-one relationship between heat

FIGURE 2

for X and smoke for Y , a construct similar to the Edgeworth box will be developed which in addition incorporates changes in the quantities of the commodities. (A decrease in heat—and thus smoke—means the community will buy more bread. The community's total bread consumption will increase according to the slope of FF .) Since tradeoffs between bread and heat are included, the Pareto welfare implications of the contract curve will be appropriate.

Suppose the consumption of the community is represented by (any) point P in Figure 2. Units of heat and bread for X are determined in the usual manner; thus X receives q units of heat and r units of bread. We require that X and Y exhaust all of their income—community consumption must lie on budget line FF . Y , then, receives q units of smoke and s units of bread. In other words, if we know the amount of bread and heat for X (represented by P), we immediately know the amount

of smoke for Y (by reading off the heat-smoke axis) and also the (residual) amount of bread for Y (the vertical distance from point P to the community budget line FF .)

Since we have indicated how to read bread and heat (smoke) consumption for any point P in the triangular Edgeworth box, it is now possible to construct indifference curves in Figure 2 from those shown in Figure 1. First, we transfer X 's indifference curves directly into the triangular Edgeworth box of Figure 2. Then, in effect we place Y 's bread axis of Figure 1 on the bread axis of Figure 2—the origin is at the intersection of community budget line FF and the bread axis. We “fold-in” the smoke axis of Figure 1 so that it lies on the community budget line FF (again with the origin at the intersection of FF and the bread axis) and “stretch” the smoke axis so that it will correspond to the horizontal scale for heat and smoke for Figure 2. This will, of course, “fold-in” and “stretch” Y 's indifference curves also, but they will retain the same general curvature as in Figure 1.

Y 's Figure 2 indifference curves will be always steeper than FF since Y requires an increase in bread to compensate for an increase in smoke. Further, since the more smoke Y has, the more bread Y will trade for a given amount of smoke abatement, the indifference curves must become steeper as Y gets more smoke. Y 's indifference curve which has been transferred to Figure 2 may be seen to meet these requirements.

The reader should note that Y 's Figure 2 “indifference curves” do not possess the usual property that the slope is the marginal rate of substitution. The algebraic slope of a Y indifference curve in Figure 1 is the negative of the marginal rate of substitution of smoke for bread at a given level of smoke and bread. A Figure 1 indifference curve with zero slope would have a slope in Figure 2 equal to the slope of the FF line, the marginal rate of transformation (MRT). This reflects the requirement that an increase in heat must be offset by a decrease in total community bread consumption. Consequently, the slope of an indifference curve for Y in Figure 2 in general will be $-MRS_{SB}^Y$ plus MRT .

Since X 's indifference curves are convex to the origin and Y 's indifference curves are concave to the origin (in Figure 2), tangencies of X and Y indifference curves will be Pareto optimal as in the standard Edgeworth box. Suppose, for example, that at point P , X is indifferent to trades at a rate of 5 breads for 1 heat; and Y is indifferent to trades at a rate of 2 breads and 1 smoke (heat). If the marginal rate of transformation is 3 breads for 1 heat, the indifference curves of X and Y are tangent since:

$$(1) \quad \begin{aligned} MRS_{HB}^X &= -MRS_{SB}^Y + MRT \\ -5 &= -(+2) - 3. \end{aligned}$$

It can be seen that no reallocation in consumption or production can make one consumer better off without making the other worse off. Thus P would be a Pareto optimum point.⁸ In the triangular Edgeworth box of Figure 2, the contract curve (locus of Pareto optimal points) is labelled as cc .⁹

II. Possible Solutions

Now that we have indicated how to interpret the curves in Figure 2, we are ready to impose a distribution of money income between X and

FIGURE 3

Y and consider several legal status quo or starting points which might obtain prior to any "negotiations" to ameliorate the effects of the externality. We will also consider the possible results of such negotiations. (In the next section we will examine government tax schemes designed to ameliorate the external effects.) In Figure 3 budget line GG reveals

⁸ Readers who are familiar with Samuelson [11, 12] will recognize the condition expressed in (1). Samuelson suggested that Pareto optimality for a public good requires the sum (over consumers) of the marginal rates of substitution of the public good for the private good to equal the marginal rate of transformation. The same condition is used for this example—which could be called a public "bad" (social evil) for consumers other than X .

⁹ We assume that heat (for X), smoke abatement (for Y) and bread (for both) are not inferior goods. Consequently, the contract curve must have a slope which is greater algebraically than that of the budget line. When Y moves to a lower indifference level along the contract curve, he must obtain more smoke and less bread. X , who will be moving to a higher indifference curve, must receive more heat, but since the total amount of bread decreases, we cannot be sure he will receive more bread.

the distribution of money income between X and Y . X 's money income will buy any combination of heat and bread represented by points on the GG line. Y 's money income will buy a quantity of bread represented by the vertical distance between FF and GG .

The examples we will consider differ in several ways. First, the legal system might permit X to generate as much smoke as he wishes; at the other extreme X might be prohibited from generating smoke without Y 's permission. Second, given a legal starting point, all of the gains from amelioration of external effects could accrue either to X or to Y . We will consider only "polar" cases; in so doing we will bracket the results which might obtain from intermediate cases.

Initially, we suppose a world in which X has the legal right to generate as much smoke as he wishes. In this case X , who independently maximizes his satisfaction, will be at E_1 on I_1^X (Figure 3). Y will be at E_1 on I_1^Y where he spends all of his money income on bread—the vertical distance between (parallel) budget lines FF and GG —and receives gratuitously smoke from X 's fire. Since I_1^X will be tangent to GG while I_1^Y must be everywhere steeper than GG , the two indifference curves cannot be tangent. Thus E_1 will not be Pareto optimal.

The shaded area between I_1^X and I_1^Y is, for the E_1 starting point, the "area of possibilities"; it includes all solutions which will not decrease the satisfaction of either consumer. In this area the contract curve is bounded by E_1^X and E_1^Y where all the gains from amelioration of the externality accrue to X and Y respectively.

Now suppose a world which prohibits X from generating smoke without an agreement with Y . Here X and Y will, in the absence of such an agreement, start on indifference curves I_2^X and I_2^Y at the intersection of budget line GG and the bread axis (E_2). This starting point reflects the prohibition of heat (smoke) production; both X and Y are spending all of their incomes on bread. If I_2^X lies above I_2^Y everywhere but at E_2 , then E_2 is a Pareto optimal corner solution. But if I_2^X is below I_2^Y in the neighborhood of E_2 , E_2 will not be Pareto optimal.

For this starting point, the shaded area between I_2^X and I_2^Y is the area of possibilities. The contract curve in this region is bounded by E_2^X and E_2^Y where all the gains from amelioration of the externality accrue to X and Y respectively.¹⁰

We have not determined what point in the triangular Edgeworth box will actually prevail. This is a (largely unresolved) problem in bargaining theory. However, when the legal starting point was altered from E_1 to E_2 , nonintersecting areas of possibilities were obtained. Thus legal

¹⁰ The possible legal starting points need not be restricted to E_1 and E_2 . If restrictions on smoke output could be varied continuously from no restriction to total restriction, the area of possibilities could include all points lying between I_1^Y and I_2^X .

interpretation may be expected to affect the final allocation of resources; only as a special case would the amount of externality (smoke) be unaltered. Of course if the marginal rates of substitution of heat (or smoke) for bread were independent of the quantity of bread (i.e., indifference curves parallel vertically), then the contract curve would be vertical and the amount of smoke would be independent of the legal starting point.

III. Taxes—1 Y and 1 X

In this section we will sketch some techniques frequently advanced for "solving" externality problems and briefly examine the properties of these techniques. In the two-person example described above, negotiations (bilateral bargaining) would seem to be the most appropriate method for ameliorating the effects of an externality.¹¹ However, since economic principles do not determine the outcome of such bargaining, this technique will not be discussed here.

Instead we will consider, in anticipation of our extension to m X -type individuals and n Y -type individuals, the solutions which would result from various tax schemes. We will presume that the individuals do not use their "monopoly power." For example, X does not recognize the effects of his actions on tax rates. He just (blindly) maximizes at the margin. Such behavior will be easier to justify when we think of a community composed of a large number of X 's; so that the isolated behavior of one individual has a negligible effect on the total quantity of smoke.¹²

In the real world we frequently encounter externality with the economy in effect operating at E_1 in Figure 4. (Smoke pollution is a possible example.) Suppose a welfare economist suggests that X should, if he wants to continue to produce smoke, be required to pay Y for the damages inflicted. That is, X 's bread compensation should be sufficient to keep Y on I_2^Y (Figure 4).¹³ One technique for achieving this goal, which enjoys the role of the standard solution, is a tax (in bread) on X per unit of smoke. The tax revenue would be given to Y .¹⁴

This per unit tax has the effect of rotating X 's budget line GG around starting point E_2 (The higher the tax rate, the steeper the after-tax budget line.) Then the effective bread price of heat is the market price

¹¹ Most of the recent literature has discussed the possibilities for negotiations, e.g., Coase [2], Buchanan and Stubblebine [1], Turvey [15], Davis and Whinston [5].

¹² For some suggestions as to how to use taxes when many individuals are involved in the example of water pollution, see Kneese [8] and Day, Dolbear and Kamien [3].

¹³ The following analysis could be carried out for other sets of assumptions. For example, X might be permitted to produce at E_1 , and Y required to compensate X for any reduction in smoke output. Such analysis is not included here since it would be mostly repetitious.

¹⁴ It is important that the tax revenue be given to Y ; the argument that Y is on indifference curve I_2^Y depends upon this transfer.

for heat plus the per unit tax on smoke. The appropriate solution will be obtained if an after-tax budget line is selected which goes through the intersection of I_2^Y and X 's price-consumption curve, pp (the locus of tangencies of X 's indifference curves and after-tax budget lines originating at E_2 .) In Figure 4, X and Y will be on I_3^X and I_2^Y respectively. However, this cannot be Pareto optimal (unless a corner solution at E_2 is appropriate) for I_2^Y will intersect the optimum budget ray and I_3^X from above, and thus not be tangent to I_3^X .¹⁵

FIGURE 4

This analysis suggests that a per unit tax on X which has the twin objectives of keeping Y on his starting point indifference curve and attaining a Pareto optimum is not, in the general case possible.¹⁶ (The tax rate which leads to a solution at the intersection of the price-con-

¹⁵ Another solution which might be considered is a tax achieving a lump sum bread transfer from X to Y for damages. In this case X will move from E_1 to a tangency with a lower "after-tax" budget line parallel to GG ; the appropriate transfer can be determined from the intersection of I_2^X and X 's income-consumption curve (the locus of tangencies between X indifference curves and budget lines parallel to GG .) The vertical distance from the lower budget line to GG represents the lump sum bread transfer. Since I_2^Y must be everywhere steeper than the after-tax budget lines, a tangency solution will not result and the lump sum tax will not be Pareto optimal.

¹⁶ I have been unable to find any welfare economists who recommend a complete set of goals and techniques for internalizing an externality. However, per unit taxes, compensation, and Pareto optimality are not uncommon classroom presumptions and they can be found individually, if not *in toto*, in the modern literature.

sumption curve pp with the contract curve would be Pareto-optimal, but at this tax rate Y would be more than compensated for smoke damages caused by X .) However, a combination of a lump sum *subsidy* and a per unit tax could be used to achieve the Pareto optimal point E_2^X on indifference curve I_2^Y . The appropriate per unit tax could be derived from the slope of an after-tax budget line tangent to I_2^Y at E_2^X ; this per unit tax will be higher than the per unit tax derived above. The vertical distance from budget line GG to the intersection of the after-tax budget line with the bread axis represents the lump sum subsidy. Intuitively, since the shape of Y 's indifference curves in Figure 2 implies that his smoke damages increase as he encounters more smoke, the appropriate per unit tax is more than enough to pay smoke damages on the inframarginal units of smoke. The steeper tax rate discourages smoke production appropriately at the margin while the subsidy holds down revenues so that Y is not overcompensated.

IV. A Digression on Information

In the tax example above it was implicitly presumed that an omniscient government or Y had full knowledge of X 's indifference curves as well as of I_2^Y . Thus the appropriate tax could be immediately determined. However, in the real world such knowledge is usually unavailable. To circumvent this information problem the government might use an iterative procedure (similar to a *tatonnement*).¹⁷ In our example the government wishes to permit X to create smoke so long as Y is adequately compensated—kept on I_2^Y . Suppose the government levies a per unit tax in terms of bread on X 's creation of heat (smoke). X responds by selecting that quantity of heat and bread which maximizes his utility. Then if the resulting quantity of smoke and tax revenue (in bread) puts Y to the east (west) of I_2^Y , the per unit tax should be increased (decreased). The final solution will, of course, be at the intersection of X 's price-consumption curve and I_2^Y .

Suppose, instead, the government seeks to insure the satisfaction of the marginal conditions necessary for Pareto optimality. It can again assume that X will be on an indifference curve tangent to his after-tax budget line. If X 's selection puts Y on an indifference curve which cuts the after-tax budget line from above (below), the tax rate should be increased (decreased). A Pareto solution will be achieved at the intersection of the contract curve and X 's price-consumption curve.

All of this can be done without knowledge of X 's indifference curves (providing X maximizes blindly). However, if Y and not the government is administering this scheme, a Pareto optimum is unlikely. Y can

¹⁷ Such a procedure was suggested by Davis and Whinston [5].

maximize his utility by selecting the tax rate where X 's price-consumption line is tangent to a Y indifference curve; this point will not be Pareto optimal. Consequently this *tatonnement* procedure would seem more applicable in situations where Y is not a self-seeking individual but represents a government authority which desires that marginal conditions for Pareto optimality be satisfied. Income redistribution can be achieved (ideally) through some other means such as lump sum transfers.

The above discussion displays techniques for improvements (in the Pareto sense) over the starting point solution when X 's indifference curves are not known. However, if this lack of information means the government (or Y) is also ignorant of the starting point, improvements may not be possible. This situation is examined in the remainder of this section.

In some applications of economic theory to externalities, it is presumed that one of the agents takes the initiative in achieving an optimum amount of externality. This (magnanimous) agent presents to the other agent a schedule of damages or benefits which will accrue to him from changes (from the starting point) in the amount of externality. The other agent then is invited to choose that amount of externality (and pay or be paid damages) which maximizes his satisfaction without reducing his "benefactor's" satisfaction below the level achieved at the starting point.¹⁸

But this "benefactor" technique is not always successful even theoretically. If Y is the benefactor and there are no legal restrictions on smoke production (starting point E_1), a difficulty may result if Y does not know X 's indifference curves. Generally, the "magnanimous" agent can derive the starting point from the law and his own preferences.¹⁹ But in this case the starting point E_1 depends on the behavior of X in the absence of any restrictions on smoke production. Perhaps Y will know this behavior historically. But if there is no history or if X 's behavior changes over time (because of changes in income for example), Y is faced with a dilemma. If X knows that Y will permit him to move along Y 's starting point indifference curve, X can maximize his satisfaction by claiming that his starting point would be an expenditure of *all* of his income on heat (smoke). This would of course put Y on an indifference level below the level of E_1 . Y will be understandably reluctant to have his generosity result in such a sacrifice. But Y has no obvious

¹⁸ For example, such a system is implicit in Kneese [8]. A (magnanimous) water authority is the counterpart of Y and a polluting firm is the counterpart of X .

¹⁹ If the law indicates prohibition, Y or X (as a benefactor) can determine his starting point indifference curve. And if the law indicates no smoke restrictions, X can determine what he (as a benefactor) would do, i.e., he can locate E_1 and indifference curve I_1^X .

way out of his dilemma. If, on the one hand, he does nothing, the non-Pareto optimal E_1 will obtain. But, on the other hand, if Y takes the initiative in achieving a Pareto optimum, he may be forced to a lower indifference level.²⁰

V. Taxes— m X 's and n Y 's

For simplicity and ease of exposition our analysis has thus far been carried out in terms of two individuals X and Y . But the exercise is much more appropriate for applications where there are many individuals such as X and many individuals such as Y . Although the resulting model is still artificial, it is an improvement in an important dimension over the bilateral case.

Suppose there are m bread and heat (smoke-producing) individuals and n individuals who live by bread alone (each must breathe the smoke produced by the m smoke-producing individuals). We need not assume equal incomes or identical tastes for either the X -types or the Y -types. Assuming that a unit of heat for any X -type consumer generates an equal amount of smoke for every Y -type consumer, the condition for a Pareto optimum is:

$$(2) \quad MRS_{HB}^{X_1} = \dots = MRS_{HB}^{X_m} = - \sum_{i=1}^n MRS_{SB}^{Y_i} + MRT.$$

Following our example of Section III, we consider the starting point where no X is permitted to produce smoke. In the absence of an agreement with the Y community, all of the X 's will spend all of their income on bread. Given the income of each X , it is a simple matter to determine the total quantity of bread which would be bought by the X community. If we also know the price ratio between heat and bread, a budget line corresponding to GG can be constructed.

The Y community will spend all of its income on bread also. Given the total income of the Y 's, their total bread consumption can be determined. This leads to a budget line corresponding to FF . For each of the Y -type individuals, expenditure of all of his income on bread would put him on a particular starting point indifference curve. A Scitovsky community indifference curve [14] (or a Samuelson minimum-total-requirements contour [13]) corresponding to I_2^Y can be obtained by summing over all Y 's the quantity of bread which would be required to keep

²⁰ A similar problem is analyzed in a paper by Kamien, Schwartz, and Dolbear [7]. In that article a profit-maximizing firm (X) finds it advantageous to create "uneconomic" pollution in order to convince the (magnanimous) water authority (Y) of a false starting point which works to the advantage of the firm in terms of income distribution. But since the increase in the profits of the firm is less than the decrease of profits of the authority (increase and decrease are measured as deviations from the result which would obtain using the "true" starting point), the solution is not Pareto optimal.

each Y on his starting point indifference curve at various levels of smoke. The resulting community indifference curve will have the same general shape as I_2^Y (i.e., downward-sloping, concave to the origin); however, it will be steeper.

The intersection of this Y community indifference curve with the X community's aggregate price-consumption curve²¹ yields the after-tax budget line which will keep the Y community at their starting point indifference levels.⁶ This solution, as in the two-person example, will not be Pareto optimal since all members of the X community will be on indifference curves which are tangent to the after-tax budget line, and the Y community indifference curve will intersect this after-tax budget line from above. Equation (2) will not be satisfied.

Although most of the results obtained in the 1 X and 1 Y example can be carried over to m X 's and n Y 's, one result cannot. It is well known that the shape of a community indifference curve depends upon the distribution of income.²² Thus a locus of tangencies between Y community indifference curves and X community indifference curves (the contract curve) cannot be obtained in the absence of information as to how the gains from amelioration of the external effects will be distributed. To be sure, Pareto optimum points exist but the problem of dealing with externality is confounded since the techniques used above for locating such points will not be effective here.

VI. Conclusions

Although the preceding analysis has been based on a highly simplified model, the following implications for real-world problems involving consumers have been suggested:

1. The amount of externality that will tend to emerge depends on the extent of legal responsibility. The distribution of the "gains from trade" should also have an effect on amount of externality. (Section II).

2. It is not simple to regulate externality with government tax schemes. Some of the standard tax proposals will not generate results that always satisfy the requirements for Pareto optimality. It is not in general possible to impose a per unit tax which will simultaneously compensate (exactly) for damages and achieve a Pareto optimum. (Sections III and V).

²¹ This price-consumption curve is the sum of the price-consumption curves of all of the X -type individuals. Each after-tax budget line leads to a point on each individual's price-consumption curve. Quantities of heat and bread are summed and these numbers generate a point on the aggregate price-consumption curve. The aggregate curve will have the same general curvature as pp in Figure 4.

²² For an expanded discussion of community indifference curves, see J. de V. Graaff [6, pp. 45-58].

3. With information deficiencies and no legal restriction on pollution (smoke), a government authority set up to offer "bribes" for the reduction of pollution may be unable to make improvements in the Pareto sense. (Section IV).

URBAN POVERTY AND LABOR FORCE PARTICIPATION

By JOSEPH D. MOONEY*

Research on the determinants of the supply of labor, long a barren area in economics, has recently made major advances as a result of a number of interesting and significant studies [2] [3] [5] [7] [8] [11] [12] [13] [14]. Concurrently, policy makers have moved somewhat from their preoccupation with macro problems, which can be said to have dominated discussion in the early postwar years, to a re-emphasis on the "old" issue of income distribution—appearing now under the mantle of the "war on poverty." The purpose of this paper is to bring together these two streams of intellectual activity by analyzing the significance of patterns of labor force participation for the poverty problem.

More specifically, this paper is concerned primarily with estimating the direction and magnitude of the relation between the overall state of the economy (as approximated by the unemployment rate) and the labor force participation rates of the urban poor. Special attention will be given to the variations in sensitivity of participation rates of married women (with husband present), to differences in non-white and white labor force behavior, and to a comparison of sensitivity (to differences in economic conditions) of participation rates among the poor and among the population at large. A profile of urban poverty in the 52 largest Standard Metropolitan Statistical Areas (SMSA's), based primarily on a racial-age breakdown, will also be presented.

Why should a study of labor force participation among the urban poor be undertaken at the present time? There are several possible reasons. Any short-run model of the economy which attempts to estimate changes in the size of the poverty class as a function of changes in GNP and/or changes in the unemployment rate [1] [4] should include estimates of the sensitivity (to changing economic conditions) of labor force participation rates among the poor. In making projections of the size of the poverty population over the next few years, it is necessary to estimate not only how many presently unemployed poor

* The author is assistant professor of economics at Princeton University. I would like to thank William G. Bowen for his many constructive criticisms and for his encouragement of the undertaking of this study. T. A. Finegan, Harold Watts, Malcolm S. Cohen, and the referee also made several helpful comments. Finally, I would like to thank the Industrial Relations Section at Princeton University for its financial support of this study. All errors remain the author's sole responsibility. This work made use of computer facilities supported in part by an NSF grant.

people will become employed but also how many who are not in the labor force at the moment will be drawn into the labor force when the unemployment rate falls.

Along similar lines, as the unemployment rate falls to low levels (3½ per cent or lower), it is important to know how the poor, one readily available source of labor, react in terms of labor force participation to improved economic circumstances. A highly negative relationship between the labor force participation rates of the poor and the overall unemployment rate would imply a large expansion of the labor force and a possible postponement of the emergence of widespread manpower shortages, as the economy moves to lower levels of unemployment. This does not mean that poor people will move into skilled positions. Those who are drawn into the labor force when the unemployment rate falls will undoubtedly take unskilled jobs, which will permit other workers to be upgraded and thus relieve some of the pressures on shortage occupations.

At a more theoretical level, this study of the relation between unemployment and labor force participation of the poor provides an indirect test of two important alternative hypotheses of labor force behavior; the "additional worker" hypothesis and the "discouraged worker" hypothesis.¹ Directly related to this issue of the responsiveness of the secondary labor force to changes in job opportunities is another substantive issue of considerable importance. An argument can be made that one of the most important routes by which an American family moves out of poverty is the acquisition of a job by a secondary worker in the family, i.e., a married woman whose husband is the primary wage earner. One might hypothesize that, as the unemployment rate falls and jobs become more plentiful, married women in poor households headed by a male are drawn into the labor force. Consequently,

¹ The "additional worker" hypothesis postulates that, as the unemployment rate rises, overall labor force participation will rise. Thus, if this hypothesis is true, the withdrawal from the labor force of an unemployed head of household is offset by the entry into the labor force of secondary earners (wife, teenage son, etc.) who are now working in order to supplement the household income. Conversely, the "discouraged worker" hypothesis postulates that labor force participation will fall as the unemployment rate rises for prolonged unemployment causes large-scale withdrawal from the labor force and thus a consequent decline in the overall labor force participation rate. Those who argue that the "additional worker" hypothesis best describes labor force behavior contend that *on balance* the "additional worker" effect offsets the "discouraged worker" effect as the unemployment rate rises. Potentially, the best data for a test of these two hypotheses are gross labor force change data, derived from the monthly *Current Population Survey*. Unfortunately, because of a variety of reasons (e.g., non-offsetting response errors) it is very difficult to establish reliable inferences about net changes from the gross data. The civilian labor force participation rate of a particular subgroup of the population is computed by dividing the total labor force of that subgroup (which equals all those employed plus those unemployed) by the total civilian population of that subgroup.

the probability that this now multiple earner household will remain in poverty declines rapidly.² Conversely, it has been argued that, when the unemployment rate rises in a particular area and the male head of a poor household is laid off, his wife will enter the labor force to acquire a job in order to supplement the family income. The latter argument implies a positive relationship between the labor force participation rates of females in poor households and the unemployment rate. In the light of this last series of observations, this paper will devote a good deal of attention to females, especially married women with husband present.

I. *The Framework of This Study*

This study consists of a cross-section analysis of labor force participation rates in the poverty areas of the 52 largest SMSA's. Presently, there exist no systematic studies of the sensitivity of labor force participation rates among the poor to changing overall economic conditions. The reason, no doubt, is that the requisite data are very hard to obtain. The monthly Current Population Survey data are not classified in such a way as to permit this kind of analysis; nor are the decennial Census results for SMSA's or for states well suited for this purpose. The best sources of data are the *Census Tract* reports of the 1960 Decennial Census which provide a wealth of socio-economic data for carefully defined geographic areas within each SMSA. Information on median income of families and unrelated individuals, age, sex, race, marital status, educational attainment, and labor force status is provided. Unfortunately, the tabular form in which much of the data are presented in the tracts precluded their use in this study. Cross-tabulations of the tract data, appropriate for a study of this kind, are simply not available.

The data on labor force status apply to all males and females (14 years of age and over) and to married women with husband present. Thus, there is no information in the tracts on labor force status by sex and race for various age categories. However, I subdivided the poverty tracts according to the percentage of non-whites who resided in a particular tract and thus reasonably accurate tests could be performed on the basis of a racial breakdown. We computed the labor force participation rates for the respective population groups within the slums of each metropolitan area by summing the civilian labor force for the

²In 1963, among all families headed by a male in which there were two earners, the per cent who were poor was 7.9. For all families headed by a male in which there was just one earner, the per cent who were poor according to the Social Security Administration's index of poverty was 13.4. These proportions were calculated from data presented by Orshansky in [9].

specified poverty tracts within each SMSA and dividing it by the appropriate civilian population figure. The magnitude of this task can be illustrated by the fact that there are 1,400 poverty tracts in the 52 SMSA's analyzed in this study. New York City alone has 167 poverty tracts according to the poverty definition which was used.

How were the urban poverty areas, ghettos if you will, identified? A somewhat arbitrary but defensible method was used. Those census tracts which had a median family income less than two-thirds of the median family income for the entire SMSA were regarded as poverty areas. The advantage in using a certain percentage of the SMSA's median family income as the poverty cut-off level is that one largely avoids the problems associated with differences in costs-of-living among the various metropolitan areas which are inherent if a particular absolute income level is used as the cut-off point. At one point I used a cut-off income for each tract equal to $\frac{1}{2}$ of the SMSA's median family income. When this lower income level was used as the dividing line, there was a large number of metropolitan areas with few or even no poverty tracts. Indeed, even when the two-thirds level was used, many of the smaller metropolitan areas had very few tracts which could be called poverty areas according to the definition. I largely eliminated this disadvantage of the definition by restricting the final analysis to just those SMSA's (52 in number) which had a total population of 500,000 or more in 1960.³ Although some urban low-income areas were excluded by the application of our definition, there is every reason to believe that the vast majority of urban slum areas are included in this study.

Within each metropolitan area, the poverty tracts were classified in the following manner. (1) All poverty tracts in which the non-white population was greater than 50 per cent of the tract's total population were grouped together and hereafter are referred to as the *N tracts*. (2) All poverty tracts in which the percentage of non-whites was less than 50 per cent of the tract's total population but greater than the percentage of non-whites in the entire SMSA constituted another grouping and hereafter are referred to as *N* tracts*. (3) The remaining poverty tracts, the residual after (1) and (2) are deducted from the total, are the white poverty areas and are referred to as *W tracts*.

The N and W tracts permit us to examine the labor force sensitivity of the urban poor on the basis of a racial breakdown. Although the N tracts do contain whites and the W tracts non-whites, the distortion which is introduced is a small one. Indeed, the vast majority of the N tracts had a non-white population which was 75 per cent or more of

³ Honolulu, on account of the special nature of its labor force and its location, was not included in our study.

the tract's total population. The N* tracts permit us to analyze the sensitivity of labor force participation in racially mixed neighborhoods.

II. *The Results*

A. *A Profile of Urban Poverty*

The first "output" of this study is a breakdown of the poverty areas in the 52 SMSA's along racial lines.⁴ Since these poverty areas, which provided the raw material for the regression analyses in this study, are of some independent interest, they are briefly summarized here. Fourteen hundred poverty tracts were analyzed and included in this study. Of the 1400 tracts, 842 had a population which was over 50 per cent non-white. There were only 248 W tracts. The remainder (310) constituted the N* tracts. The number of poverty tracts in which the non-white population was 50 per cent or more of the population was more than 50 per cent of all poverty tracts in 31 of the 52 SMSA's. Those SMSA's which had a relatively large number of poverty tracts in which the non-white population was greater than 50 per cent of the tract's total population were mainly those metropolitan areas which had a large non-white population (Baltimore, Birmingham, Chicago, Cincinnati, Cleveland, Memphis, New Orleans, St. Louis, and Washington, D.C.). Milwaukee with a relatively small non-white population (5.3 per cent of the total) experienced an enormous increase in its non-white population between 1950 and 1960 (185.5 per cent).

The areas that had a relatively small number of poverty tracts in which the non-white population was more than 50 per cent of the tract's total population are largely in the Far West or the South West (San Antonio, Phoenix, San Diego, San Jose, Sacramento, Seattle, etc.). Here, the poverty problem in ethnic terms is largely a Mexican-American problem. Mexicans are listed as whites in the Census.

When we "plowed" through the tracts, we did record the median age of the male and female population in each tract. Forty-five of the fifty-two SMSA's had white poverty tracts. The median age of the median ages for the poverty tracts in 21 of these 45 SMSA's was over 40. Thus, the urban poor population in America's largest cities consists mainly of non-whites, Mexican-Americans, and elderly whites.

The mean labor force participation rates of all males, all females, and married women (husband present) in the poverty tracts followed a definite pattern. The mean labor force participation rates of each of

⁴Mimeographed tables, which list the number of poverty tracts for each SMSA, a breakdown of the poverty tracts by race, the range of cutoff median incomes, the percentage of non-whites in the poverty tracts in each SMSA, and a variety of other information are available from the author, Industrial Relations Section, Princeton University, Princeton, New Jersey, 08540.

the non-white groups (N Tracts) were substantially higher than those of the white groups (W Tracts). For example, in the N tracts the overall mean labor force participation rates of all males and all females were 72.8 and 41.1 respectively. In the W tracts, the rates for all males and all females were 67.3 and 35.2 respectively. The higher labor force participation rates of poor non-white females relative to poor white females is not surprising and parallels the national situation. What is surprising is the fact that poor non-white males have a higher labor force participation rate than poor white males. This differential is explained in part by the fact that many urban white poor are over 65 and

TABLE 1—RESULTS OF SIMPLE REGRESSIONS FOR THE MALE POVERTY POPULATION IN ALL SMSA'S OVER 500,000 IN POPULATION

| Type of Poverty Tract ^a | All Males 14+ | | |

| All Poverty Tracts (n=52) | -1.47 ^b | 2.25 | .09 |

^a Explained in text above.

^b Significant at the .05 level.

thus out of the labor force. Other factors which are subsequently discussed may also explain this differential.

B. Sensitivity of Male Participation Rates

Because males between the ages of 25 and 54 form such a large fraction of the total male labor force and because this group tends to be in the labor force come good times or bad, it would be surprising if the variable (the SMSA unemployment rate)⁵ used in this study explained very much of the inter-SMSA differences in the labor force participation rate of males (14 years of age and older). Table 1 presents the results for all males living in the poverty areas in the 52 SMSA's with

⁵ This is the unemployment rate in the SMSA during the census month in 1960. The SMSA unemployment rate is used because it is the "best" single indicator of economic conditions in a particular area.

500,000 or more in population. The form of the simple regression was:

$$(1) \quad Y_i = a + bX_1$$

Y_i = the labor force participation of the i th group
(e.g., all males (14+) living in N tracts)
 X_1 = the SMSA unemployment rate.

A weak but statistically significant negative relationship appears for all males living in N tracts. This same pattern is reflected in the results for all poverty tracts (= the sum of the N, N*, and W tracts).

TABLE 2—RESULTS OF SIMPLE REGRESSIONS FOR THE FEMALE POVERTY POPULATION IN ALL SMSA'S OVER 500,000 IN POPULATION

| Type of Poverty Tract ^a | All Females (14+) | | | Married Women (Husband Present) | | |
|------------------------------------|----------------------------------|--------------|-------------------|------------------------------------|--------------|-------------------|
| | Regression Coefficient (b) | "t" Value | (R ²) | Regression Coefficient (b) | "t" Value | (R ²) |
| N Tracts (n=45) | -3.61 ^b | 4.6 | .33 | -4.52 ^b | 5.7 | .43 |
| N* Tracts (n=49) | -2.55 ^a | 2.63 | .12 | -1.84 ^a | 2.39 | .11 |
| W Tracts (n=45) | -1.54 | 1.65 | .06 | -1.59 | 1.75 | .07 |
| All Poverty Tracts (n=52) | -3.14 ^b | 4.81 | .32 | -3.09 ^b | 4.3 | .27 |

^a Explained above in text.

^b Significant at the .01 level.

^c Significant at the .05 level.

Simple regressions in the same form were also run for *all males* by race living in the same 52 SMSA's. Although once again the signs of the regression coefficients were negative, none of them was significant at the .05 level—not an unexpected result. One tentative conclusion based on these findings is that the sensitivity to changing economic conditions of the labor force participation rate of low income urban male workers tends to be greater than that of the average urban male worker.

C. Sensitivity of Female Participation Rates

In this section, the sensitivity of the labor force participation rates of all poor females (14+) and subgroup, married women with husband present, will be analyzed. The results presented below in Table 2 are those obtained from simple regressions of the form:

- (2) $Y_i = a + bX_i$
 Y_i = the labor force participation rate of the i th group
 (e.g., all females (14 +) living in N tracts)
 X_i = the SMSA unemployment rate.

An examination of the results in Table 2 reveals an interesting pattern. The most significant relationship exists for non-white married women with husband present. A highly significant relationship also exists for all non-white females, a group which includes, of course, non-white married women (with husband present) as a subset. A regression coefficient of -4.52 implies that an increase of one percentage point in the overall unemployment rate of the SMSA leads to a decline of $4\frac{1}{2}$ percentage points in the labor force participation rate of non-white married women (with husband present). This result can be construed not merely as inconsistent with the "additional worker" hypothesis but as strong support for the "discouraged worker" hypothesis, at least with reference to non-white married women (with husband present). In other words, although there may be some non-white females who enter the labor force when the unemployment rate rises, on balance they are more than offset by the discouraged females who withdraw from the labor force when the unemployment rate rises.

An examination of the mixed tracts and the white poverty tracts reveals that the sizes of the regression coefficients and the R^2 terms decline sharply. On the basis of a comparison between the mixed tracts and the white tracts, one possible conclusion is that the reduced significance of the relationship for the mixed tracts is a result of the increase in size of urban white poor within this classification.⁶ This latter observation suggests the following question: Why are the labor force participation rates of urban white poor females and married

⁶ Another way of depicting the influence of the size of the non-white poor population on the sensitivity of the labor force participation rate of all poor females is by means of an interactive model. One such model is the following:

$$Y = a + b \left(c + d \frac{N}{P} \right) X.$$

Y = labor force participation rate of all poor females in each SMSA; N/P = per cent of the total poor population in each SMSA who are non-white; X = SMSA unemployment rate. When this model was tested, the result was:

$$Y = .53 - 3.46 X + .90 \left(\frac{N}{P} X \right). \quad R^2 = .36$$

(.66) (.45)

Thus, the change in the labor force participation rate of all poor females with respect to a change in the SMSA unemployment rate is a positive function of the per cent of the poor population who are non-white. This checks with the results presented above and provides strong support for them.

women less sensitive to changes in economic circumstances than those of non-white females? At least two reasons are possible.

1. The poor white females are much older on the average than their non-white counterparts. A significant number of all urban white adult poor are over 65 and of this age group the vast majority are females.⁷ Presumably, many of this latter group have permanently withdrawn from the labor force and thus their labor force status is virtually insensitive to changes in economic circumstances.⁸

2. Another explanation pertains to a possible but speculative characterization of urban white poor. Unlike the non-white population, the white population in this country has not been subjected to over 300 years of continual discrimination, injustice, and denial of equal opportunity. The question naturally arises—why was the white population in this study unable to take advantage of the opportunities afforded them? Some obviously were the victims of temporary economic setbacks—for example, laid off auto workers in Detroit, or laid off defense workers in San Diego. The poverty of this group is quite likely of short duration and it does not really belong in this study. This is not meant to minimize the hardships associated with this type of economic calamity. Poverty and lack of employment among other urban whites, however, may have been caused by a more complex set of circumstances. Low I.Q., physical disabilities, mental illness, alcoholism, and narcotics addiction are a few of the debilitating factors which come to mind. Of course, non-whites are not strangers to these sundry disabilities but their incidence may be higher among poor urban

⁷ A special tabulation of the poverty population, based on the March 1965 *Current Population Survey*, discloses that (i) of the total number of non-farm white poor over 22 years of age, 37 per cent were over 65, (ii) of the total number of unrelated individuals who were white, poor, and over 65, almost 80 per cent were females (1.9 million out of a total of 2.4 million persons). These data were provided by the Office of Research, Program Planning, and Evaluation in the Office of Economic Opportunity.

⁸ The search for a suitable age variable for the regression analysis in this study was unsuccessful. The only age measure which is available from the tracts in a usable form is median age broken down by race and sex. The non-white median ages fall within a narrow range, largely within the 22-30 age bracket, and thus would be of little value in attempting to explain inter-SMSA differences in labor force participation of non-whites in N tracts. An aggregation problem affected the N* tracts. The N* tracts, consisting of younger non-whites and older whites often in roughly equal numbers, likewise did not present a great deal of dispersion in their overall median ages. Since the N* tracts do consist of whites and non-whites, it would not be legitimate to use either the white or non-white median age alone to test for differences in labor force participation. For white females in the W tracts, the range of median ages was very broad (18.2 in San Antonio to 69.9 in Tampa-St. Petersburg). However the relationship between age and white female labor force participation is bimodal in nature. The labor force participation rate for all white females peaks at the age of 20 or thereabouts, declines until the mid-30's, and then rises to another peak around age 50. The upshot of all this is that a linear regression with the white female labor force participation rate as the dependent variable and median age as an independent variable would be of little interest and very difficult to interpret.

whites. If a population subgroup were subject to one or a combination of these factors, the insensitivity of their labor force participation rates to changing economic conditions is explicable. The prospect of a job is not sufficient to draw them back into the labor force. Indeed, a job alone is not the major solution for their poverty-related problems.

This admittedly speculative explanation is indirectly borne out by Locke Anderson's study [1, p. 523] which analyzes changes in median family income of different family types as a function of changes in aggregate income. Anderson finds that the median income of non-white, non-farm families headed by a male < 65 has a high elasticity with respect to aggregate income, whereas the same elasticity for white non-farm families headed by a male < 65 is much lower. The insensitivity of the labor force participation rates of white urban poor females to changing economic conditions lends support to Anderson's findings.

In the results presented below in Table 3, the analysis has been broadened to include a demand variable.⁹ This demand variable based on the distribution of female employment among various industries, is designed to take into account the differences among local labor markets in their demand for female labor. A local labor market such as Pittsburgh with a heavy industry base has a rather low demand for female labor (the demand variable for Pittsburgh equals .293) whereas Washington, D.C. with its government employment base has a much higher demand for female labor (the demand variable for Washington, D.C. equals .382). One long-run effect of a situation such as Pittsburgh's should be noted. If the local industries hire only males and thus create a shortage of jobs for women, the surplus pool of female labor may tend to attract industries with complementary labor demands. The classic examples of this phenomenon are the silk mills in Pennsylvania coal towns and shoe and textile industries in the New England port towns [15, p. 42].

Table 3 presents the results of the multiple regressions for the pov-

⁹ For a complete explanation of the construction of this demand variable, see W. G. Bowen and T. A. Finegan [2, pp. 157-58]. In their own words—"We calculated the ratio of female employment to total employment in each of some 35 two- and three-digit industries for the United States as a whole. Taken together, these industries contained all the employed persons in the civilian labor force during the census week. Second, for each individual metropolitan area, we multiplied the total employment (of both sexes) in each industry group by the national female-employment ratio for that group as calculated in step one. Finally, the products obtained by step two for each city were summed and divided by the total civilian employment in the city. Each quotient is simply a weighted average of the national female employment ratios for the industries in each city. What it shows is the female employment ratio we would predict each city to have in a given year if this ratio depended only on the city's industry mix. The actual ratio, of course, will be affected by many other factors." Professors Bowen and Finegan were kind enough to put this index at my disposal.

TABLE 3—RESULTS OF MULTIPLE REGRESSIONS FOR THE FEMALE POVERTY POPULATION IN ALL SMSA'S OVER 500,000 IN POPULATION

erty population in the 52 largest SMSA's. The regressions were of the following form:

$$(3) \quad Y_i = a + bX_1 + cX_2$$

Y_i = the labor force participation rate of the i th group
(e.g., all females (14 +) living in N tracts)
 X_1 = SMSA unemployment rate
 X_2 = the demand variable.

The addition of the demand variable significantly improves the simple relationship in two cases—all females (14+) in N tracts and married women (with husband present) in N tracts. The R^2 for all females in N tracts increases from .33 to .47 and for married women (husband present) from .43 to .48. The pattern which was evident in the simple regressions reappears. Although the addition of the demand variable has reduced somewhat the size of the negative regression coefficient of the SMSA unemployment rate for females (14+) and married women

(husband present) in N tracts, in both cases the coefficient is still significant (at the .01 level) and quite high. The demand variable for these latter two groups is also significant at the .01 level and .05 level respectively.

In the N* tracts and the W tracts, the amount of variance explained by our regressions, as indicated by the R^2 terms, is very small. Although the regression coefficients of the unemployment rate are significant at the .05 level in a couple of cases—all females living in N* tracts and married women (husband present) in W tracts, the demand variable is negative for both groups in the W tracts and the R^2 's insignificant at the .05 level. The fact that the coefficients of the demand variables for poor white females and married women in W tracts have negative signs is consistent with the view presented in this paper that many of them are for one reason or another (age, debilitating personal attributes, etc.) largely bypassed by economic progress. The contrast between the results for the N tracts and the result for the N* and W tracts is simply striking.

In order to provide a reference point for comparison purposes, exactly the same regressions were run for all females (14+), non-white females (14+), white females (14+), and married women (husband present), all non-white married women (husband present), and all white married women (husband present) in the 52 largest SMSA's. These groups naturally include the poverty populations analyzed above. The results are presented in Table 4. The fit is consistently better for these groups than for comparable groups within the poverty population. The regression coefficients of the unemployment rate are always negative and significant at the .01 or .05 level in every case, save all white females (14+). There can be little doubt that the discouraged worker hypothesis also describes the labor force behavior pattern of the general populations as well. Note, however, that the negative regression coefficients of the unemployment rate for the poverty populations, especially the non-white groups, are larger in almost every case than the same coefficients for the population as a whole. It seems clear that the low income worker is more likely to be a discouraged worker than an additional worker especially if "she" is a non-white married woman with husband present.

III. *Conclusions*

Before drawing any conclusions from the results presented above, at least a few caveats should be posted. There has been no attempt to introduce into our analysis a control variable such as the number of teenagers (by sex and race) enrolled in school. Exactly 1,400 poverty tracts would have to be analyzed and the computation of these variables simply lies beyond the ambitions of this study. Furthermore, no account has been taken of the role of migration in affecting labor force

TABLE 4—RESULTS OF MULTIPLE REGRESSIONS FOR THE ENTIRE FEMALE POPULATION IN ALL SMSA'S OVER 500,000 IN POPULATION^a

| Population Groups | X_1 =SMSA Unemployment Rate | | X_2 =The Demand Variable | | |
|---|---|--------------|---|--------------|-------------------|

Sources: The population and labor force data used in these regressions were obtained from U.S. *Census of Population 1960*, "General Social and Economic Characteristics by State," PC (1) 6 (c) and U.S. *Census of Population 1960*, "Detailed Characteristics by State," PC (1) 32 (D).

participation rates [8, pp. 80-81]. Clearly, migration to areas of low unemployment rates is an alternative to withdrawal from the labor force in areas of high unemployment rates. In the light of this, it is quite probable that our estimates of the sensitivity of labor force participation rates are too high. It would be desirable to include in our analysis an appropriate migration variable. However, the task of constructing appropriate net and/or gross migration rates for specific groups by age, sex, race, and marital status, which would be applicable to the poverty areas in each of 52 SMSA's, would be a major undertaking in itself. Let it suffice to say that, if labor market theory has anything valid to say about population movements, then the regression coefficients for the unemployment rates are biased upwards somewhat.

An additional qualification should be noted. The cross-sectional analyses in this study probably represent the accumulation of labor force adjustments to long-range differences in economic opportunity

and social factors in addition to short-run cyclical variations. Thus it is not entirely legitimate to use the estimates of labor force sensitivity presented in this study to project short-run changes in labor force behavior over the cycle. Nevertheless, there is a certain amount of support in the time series information for the results presented herein.¹⁰ For example, from 1961 to 1965, the annual average total unemployment rate fell from 6.7 per cent to 4.6 per cent. Over the same period, the labor force participation rates of all non-white females (ages 20-64) rose from 54.3 to 56.2. The labor force behavior of non-white females (ages 20-34) provides more compelling support for the results presented herein. From 1961 to 1965, the labor force participation rate of non-white females (ages 20-34) rose from 50.0 to 54.4. On the other hand, if one searches the time series data carefully over a longer period, one can find some evidence of counter-cyclical labor force behavior of non-white females.

With these qualifications in mind, the basic conclusion which can be drawn from the above findings is that the average non-white family with both husband and wife present attempts to lift itself out of poverty during prosperous times by becoming a multiple-earner family. The high sensitivity of the labor force participation rate of non-white married women with husband present means that, as the unemployment rate falls, they enter the labor market to secure a job—either part-time or full-time. By our estimates, their labor force participation rate rises by approximately three percentage points with a one percentage point fall in the unemployment rate. During the day, young children presumably are left with relatives or at day care centers, while the mother goes to work. If their husbands are presently working, their wages rise somewhat during the course of an upswing in economic activity. Thus, the combination of rising wages on the part of the employed husband and increased labor force participation on the part of the wife act to lift the non-white urban family above something called a "poverty line."

For all non-white females (those living in N tracts), the negative

¹⁰ One recent example of a sophisticated time series study was done by Dernburg and Strand [12, pp. 71-96]. Using an employment-population ratio and an unemployment compensation exhaustion ratio as independent variables, Dernburg and Strand estimate the elasticities of labor force-population ratios of particular groups with respect to the overall employment-population ratio. They estimate a full-employment labor force based on a "conservative" definition of full employment equal to a 4 per cent unemployment rate. Using their full-employment labor force estimate, they are able to estimate hidden unemployment equal to the estimated full-employment labor force minus actual unemployment. The finding of the Dernburg and Strand study which bears directly on this study is the higher elasticities or higher sensitivities of the adult female labor force with respect to total employment relative to the adult males. However, Dernburg and Strand do not classify the labor force according to color or income level, both of which are of direct concern to this study.

regression coefficient of the SMSA unemployment rate is less than the same regression coefficient for non-white married women (in the N tracts) in both the simple and multiple regressions. The "discouraged worker" effect is clearly much stronger for non-white married women (with husband present) than it is for all non-white females. One explanation for this result may lie in the fact that a large number of non-white females over 14 years of age who are not married women with husband present are female heads of families and many of this latter group are on the public assistance rolls. Under the existing means tests for recipients of public assistance, the amount of assistance is an estimate of minimal needs minus any earnings which the family makes. The upshot of this means test is that it taxes earnings at 100 per cent. Thus, public assistance contains a strong built-in disincentive to work. Consequently, it is not surprising that a tightening labor market does not necessarily induce them to enter the labor market.

The "backwash" thesis concerning poverty in America asserts that the economy may prosper and grow as in the past but the "other America," a hard core of poor beyond the reach of a growing economy, will be stranded behind and thus bypassed. On the basis of the findings in this study, the "backwash" thesis may have some relevance as far as poor urban white families are concerned but it does not apply to poor urban non-white families with both parents present. A tighter labor market not only means better jobs, higher wages, and longer hours for workers, but it also draws workers into the labor force, especially non-white females who were not in the labor force when prospects for finding a job were much dimmer.

Finally, it has been said that real improvement in the economic status of Negro men and in the stability of Negro families would probably lead to a reduction in labor force participation by Negro women [16, p. 882]. A "real improvement," say a 5- to 10-year period with the non-white male unemployment rate 4 per cent or lower, would probably lead to a reduction in the very high labor force participation rates of non-white women. Over the range of unemployment rates encompassed by this cross-sectional study (largely between 8 per cent and 3.5 per cent) there is no evidence, however, that Negro women withdraw from the labor force as general business conditions improve. We will simply have to wait until that state of true full employment is reached and *maintained* to test for the other possibility.

MIXED PUBLIC AND PRIVATE FINANCING OF EDUCATION: EFFICIENCY AND FEASIBILITY

By MARK V. PAULY*

Governmental support for basic education is rarely questioned; this consensus has long been institutionalized in the American public school system which, ideally, provides each child with access to *equal* publicly supported facilities. Questions have been raised concerning the efficiency of organization, and public operation has been criticized. No one has demonstrated, however, that there are inefficiencies inherent in *equal* provision of public support to each student, whether facilities be publicly or privately operated. This paper will show that, if efficiency considerations are controlling, ethical canons of distribution being neglected, *unequal* public support is necessary under most plausible circumstances. The argument does not depend on differentiation of children according to ability to learn; in the analysis all children are assumed equally capable of benefiting from education. The argument depends critically on the distinction between marginal and inframarginal externalities.

I

In the modern theory of public finance, a pure public good is defined to be a good every unit of which produced is equally available for consumption by all [11]. A necessary condition for optimality in the production of such a good is:

$$(1) \quad \sum_{i=1}^m u_p^i / u_r^i = F_p / F_r$$

where the term on the lefthand side of the equality represents the summation (over all m persons in the community) of the ratios of each person's marginal utility from public good X_p to his marginal utility from some private (numeraire) good, and the term on the righthand side represents the ratio of the marginal cost of the public good to that of the numeraire good. That is, condition (1) states that the marginal rates of substitution summed over all persons must equal the marginal rate of transformation, or, more crudely, that the summed marginal evaluations must equal the marginal cost.

* The author is a graduate fellow in economics at the University of Virginia. He is indebted to Professors James M. Buchanan, Gordon Tullock, and Thomas Borcherding for many helpful comments.

It is clear that such services as education do not fall under the strict Samuelson definition of a public good. Full exclusion is possible; a desk occupied by one child cannot be occupied by another. Education is provided or financed publicly, therefore, not because the technical considerations of production make it difficult to exclude others from the consumption of it, but rather because persons other than the direct consumers of education (the child, or, more generally, his family unit) derive benefit from that child's consumption of educational services.

This idea is usually expressed by saying that some kinds of education—citizenship or literacy-oriented education—generate spillover or neighborhood effects which benefit persons other than the direct recipients of the education.¹ While “everybody stands to gain from living in a more educated community,” the child or his family clearly benefits more from his consumption of educational services than does anyone else.² The basic reason for public provision of education is not that it is impossible to exclude anyone from the consumption of educational services, but that consumption of such services by any child confers benefits on everyone else; the external economies are those arising from consumption per se.

This type of externality in consumption requires a utility function (assumed, for simplicity, to be attached to families) in which there enter as arguments not only the consumption of education and all other goods by the family itself, but also the consumption of education by *all other* families in the community. If X_{pi} represents the amount of educational services consumed by the i th family, a typical utility function for the i th family consuming n goods plus education in a community of m persons is as follows:

$$(2) \quad U^i = U^i(X_{1i}, X_{2i}, \dots, X_{ni}; X_{p1}, \dots, X_{pi}, \dots, X_{pm}).$$

Note that the consumption of education by each one of the other families constitutes a separate “public good” in family i 's utility function.³

Each family thus has a potentially positive marginal rate of substitution between another family's consumption of education and the goods it consumes itself. The optimality condition (similar to condition (1)) is that these marginal rates of substitution summed over all families must

¹ See the discussion by Milton Friedman [5] [6, pp. 85–98] and others [10] [12]. B. A. Weisbrod also discusses spillover effects [13], but he is mainly concerned with those of a geographical nature.

² R. A. Musgrave [9, p. 13] considers education to be a “merit want” that involves substantial elements of social wants, but it is difficult to be sure just exactly what he means by a merit want. See also Head's development [7].

³ This procedure allows all “impure” public goods and even purely private goods to be analyzed as public goods. It has been developed by James M. Buchanan in his manuscript [1].

equal the marginal rate of transformation. That is, for the good X_{pj} , the education of the j th child, optimality requires that the following condition holds:

$$(3) \quad \sum_{i=1}^m u_{pi}^i / u_r^i = F_{pi} / F_r.$$

Generally, family j will have the highest marginal rate of substitution between child j 's education and the numeraire good (that is, the highest marginal evaluation of the education of child j), but other families as well may have a positive marginal evaluation of child j 's education. A positive marginal evaluation for other families indicates that, if provision of child j 's education is left solely to family j , marginal external benefits to other families may exist which could be obtained by some community provision of education to child j .

II

The procedure for conceptually determining the optimum amount of community payments for the education of any child would appear simple. Given the amount of education provided by the parents, if the rest of the community evaluates positively an additional unit of education to a child, the community should provide a subsidy for education, an addition to the parents' expenditure, until the education of that child is extended up to the point at which condition (3) above is satisfied.

Satisfying this optimality condition is far from simple, however, because the externality generated by consumption per se of education is what has been termed a "reciprocal externality" [2]. That is, the amount of benefit an additional unit of education for child j would confer on the rest of the community depends on how much education family j has already provided for its child on its own, and at the same time family j 's decision whether to make expenditures for additional education for its child depends on how much the community has spent. The presence of this sort of externality raises the possibility of the non-existence of equilibrium [4], and of the nonexistence of a uniquely optimal result. The outcome depends on the bargaining skill, the adroitness in concealing preferences, on the parts of family j and of the community.

This problem can be illustrated as follows: Suppose the community initially provides zero educational services. The family units will allocate their budgets among education and all other goods in such a way that they maximize their utility. Education will be provided for each child by his own family up to the point at which $u_{pj}^j / u_r^j = F_{pj} / F_r$. Assume that education is a normal good, and that all parents of equal income levels wish to provide equal amounts of education for their children

(that is, identity of tastes as regards education), so that families with low incomes will be consuming small amounts of education, and families with large incomes large amounts. If the community now "wakes up" to the possibility of obtaining benefits from the provision of additional education, the benefit to the community (that is, the marginal evaluations summed over all families except family j) for expenditures on additional education to be provided to child j will be greater the smaller the amount of educational expenditure made by child j 's parents, so long as the community's demand or marginal evaluation curve is negatively sloped. It is possible that some parents with large incomes will have made on their own large enough expenditures on education so that the community evaluates additional education for their child at zero. In such a case, though provision of education to a child confers benefit on the community, it does so only inframarginally. However, for those parents with low incomes who provided only small amounts of education (possibly zero) for their children, the public supplement will be large, and will diminish as the parents' income increases. In such a case, the externalities are marginal. But this is an equilibrium situation only if the parents continue to provide for their children the amount of education they would have provided when community expenditures were zero, which is unlikely—the education provided by the community will doubtless substitute for some of the education provided by the parents.

If, however, we suppose that all parents initially provide no education for their children, then the amount the community will provide in maximizing its utility will be the same for every child. The value to the community of one literate and patriotic citizen is about equal to the value of any other. This equal provision will be optimal only if the parents cannot or will not provide education on their own. If parents will provide supplements to the state financed amounts, to allow such payments is clearly Pareto-optimal, since only those parents making the expenditures need bear the incremental costs. If institutional arrangements are such as to make such supplementary financing extremely difficult, inefficiency clearly characterizes the result. Such a situation approximately corresponds to that of the present public school system, in which socialization of the schools (and consequent public aid only to public schools) has resulted in such high cost in terms of public aid lost to parents who would wish to supplement their child's education (and who can do so only by sending him to a nonpublic school) that most do not do so.

The inference here might seem to be that optimality could be introduced by allowing each parent who desires it to receive a voucher of

value equal to the per-pupil expenditure within the public school system, which voucher would be of the same size to all parents.⁴ If such vouchers were given, each family would extend its own expenditures up to the point at which its own marginal evaluation of an additional unit of education for its child (given the total amount provided by it and by the community) equalled the marginal cost. But since the community's marginal evaluation, though lower than it was when family expenditures were zero, may very well still be positive, this position may still be nonoptimal

$$\left(\text{that is, } \sum_{i=1}^m ME > MC \right).$$

Moreover, the community's evaluation of an additional unit of education to any family will have fallen more the more expenditure for education that family had made on its own, and the community will readjust its own payments accordingly.

Whether we begin with level of parental expenditure when community expenditure is restricted to zero, or with level of community expenditure when parental expenditure is restricted to zero, removal of the restriction, and consequent increase in community expenditure in the first case, and in parental expenditure in the second, will lead to a reduction in expenditure by the other party. Hence, we can conclude that simple removal of the restriction on community or parental expenditure (by a voucher scheme, for instance) will not lead to a Pareto optimum, but will lead to a further process of adjustment and readjustment on the parts of community and parents. It is impossible to specify the optimal amount of community expenditure for any child's education without knowing the community's and the parents' choice functions, and the types of bargains struck in getting to optimality.

III

By making some assumptions about these choice functions, and by assuming away strategic behavior, we can indicate the nature of an optimal solution. The crucial assumption here will be that the community's demand curve for education is (almost) perfectly inelastic in the relevant range, and that there are zero income effects on the community's choice function from different levels of parental provision. This is equivalent to assuming that families, in their capacity as members of the community, have a minimum or "target" amount of education they

⁴ See, for instance, André Danière's discussion [3]. A voucher system with the vouchers of equal value to all families has actually been used in the State of Virginia for several years, and is described in [15].

wish to see provided to each child—an amount which is considered (a) the minimum necessary for good citizenship and (b) the maximum amount the community would wish to provide for citizenship-oriented education at any positive price.

Refer to Figure 1 below. The solid lines are the result of the following conceptual experiment: Families at different income levels are confronted with varying amounts of community expenditure for their

FIGURE 1

children's education (given as lump sums), and are allowed to adjust their own expenditure to maximize their utility. It is assumed that no family is taxed to provide education for its child, that the amount of community expenditure represents the contributions of persons other than the child's parents. The assumption that education is a normal good and that all families have the same tastes for their children's education means that families 1 through 4 are arranged in ascending order of income. These choice lines (drawn linear, though they need not be) must have an absolute slope greater than unity, since each family will

doubtless wish more education when it is provided to it "free" by the community than when it must pay the full marginal cost of it, so long as education is a normal good.

The dashed line QR represents the various outlays on education that will be made by the community for various outlays made by the parents. This line has an absolute slope of one, based on the a priori assumption made above of a "target" amount of education. Thus if the parents spend nothing on their own (the assumption underlying the public school system), the community will spend OQ for each child. If the community spends OQ , but the parents are allowed to provide additional amounts (the voucher system), family 3, for instance, will spend OU . But if family 3 spends OU , then the community should optimally spend only OW ; if the community does in fact spend OW , family 3 will spend OX , and then the community will spend OF , and so forth. A series of adjustments and readjustments by the community and each family occurs, but it can be seen that the process is converging to an equilibrium.

The equilibrium payments by and for each family are given by the intersections of QR with the choice lines for each family. (For family 1 the community would pay the full cost of education; family 4 would pay the full cost on its own.) It can be seen that the community payments will vary inversely with income. These equilibria are also optimal. At all quantities of education less than at the intersections, the marginal evaluations of the community and of the family exceed the marginal cost, so that expansion in quantity is indicated. For quantities of education above the equilibrium amounts the marginal evaluation of the community falls to zero, and that of the family is less than the marginal cost, so that optimality requires a reduction in quantity. Only at the intersections, where the marginal evaluation of the community is zero, and that of the family is equal to marginal cost, is condition (3) above satisfied. For families with incomes high enough that they provide all of the minimum basic education on their own, the community should optimally make zero expenditures.⁵ For families with incomes so low that they make no expenditures on education, no matter what the community does, the optimum payment is the minimum basic amount. For families with incomes in between, the optimum community payment

⁵ E. G. West [14] seems to make the same assumption that was made here—that there is a minimum amount of education in which the community is interested, and that it has zero demand for education for any child beyond that point. He further claims that, in fact, almost all families are in the position of family 4, having incomes sufficiently large that they would provide the minimum basic amount of education if there were no community provision of education to them and if their current taxes were reduced by the amount they now pay for their child's education. He does not recognize, however, that for those who receive community payments, these payments should vary inversely with income. See also Mill's comments [8, pp. 190–91].

should vary inversely with the fraction of the minimum basic amount provided by the parents' expenditure. That is, it should vary inversely with income.

This solution, it must be admitted, arises only because of the peculiar form given to the community's choice function. But since it seems a fair conjecture that the community's demand curve for citizenship-oriented education is very elastic, if not perfectly so, and that income effects of parental expenditures are negligible, this result is interesting.

IV

Let us consider the more general case in which the community's demand curve for education, though downward sloping and probably inelastic, is assumed to depart somewhat from perfect inelasticity, and income effects are positive. A diagram could be drawn for this case in which QR would have an absolute slope of less than unity, and it would again show a series of independent-adjustment equilibria. Again, the equilibrium amount of community provision would vary inversely with income.

But now these equilibria are not optimal. The community and the parents adjust independently until *each* of their marginal evaluations equals the marginal cost. Hence, the sum of these two evaluations

$$\left(\sum_{i=1}^m u_{pm}^i / u_r^i \right)$$

exceeds the marginal cost. What is necessary to get optimality is an agreement between the community and each family to share the cost of providing additional education for each child. Unless the cost of reaching such agreements is prohibitive, this is the typical public good case in which the sharing scheme at optimality is, strictly speaking, indeterminate.

Intuitively one would suppose that, since in independent-adjustment equilibrium (which can always be reattained by the community) payment by the community varies inversely with income, if the same "kinds" of bargains are struck at all income levels, a similar pattern will have to be exhibited at the optimal point.⁶ One possible sharing scheme which does give this result is based on the assumption that the community's share is to be kept as small as possible. This assumption is

⁶ If the parental demand curve for education were very elastic at high-income levels, it is conceivable that, under some sharing schemes, the community might be led to pay subsidies varying directly with income, since a small subsidy from the community could trigger such a large increase in parental outlay that the community would wish to increase its payments. But since all parental demand curves for education are likely to be inelastic, this situation seems implausible.

made for three reasons: (1) Since the community can adjust more freely than can individual families, it can get a bargain more in its favor. (2) The process of providing a service through the fisc is likely to entail high tax collection costs. (3) Most importantly, since lump-sum taxes are not likely to be practical, almost any method of public provision through tax and expenditure involves some excess burden; any feasible tax will cause some distortion. Hence, any reduction in the extent of public provision will reduce this burden [2].

Refer to Figure 2; the ΣD curves are the vertical summations of the

FIGURE 2

community's demand curve with the demand curves for each family. Income effects are ignored here. The optimum quantities of education are OQ_2 for families 1 and 2, OQ_3 for family 3, etc. (Family 1 is so poor it has no perceptible demand for education at any positive price.) Since the community can, in effect, vary the price per unit to the families, it can get them to make payments equal to the area under their demand curve below its intersection with the cost line (e.g., $OCEB$ for family 2). Then the amount the community will have to pay to get the provision of education extended up to the point at which condition (3) is satisfied is the whole rectangle OQ_2AB for family 1, area CQ_2AE for family 2, triangle FGH for family 3, triangle LJK for family 4, and zero for family 5. Note that the size of these areas varies inversely with income.

The amounts that the community should pay in an optimal situation are, of course, the result of a bargaining process, and it is conceivable, given only condition (3), that the community could optimally pay the same amount to all. But this would require a unique sort of bargaining behavior which is unlikely to occur, if the community were free to adjust. Equal community payments to all would involve more favorable bargains for those with high incomes, and less favorable bargains for those with low incomes. It is unlikely that the community would permit such bargains to be struck.

Actually attaining the optimal result may be difficult, since lump-sum payments like those in Figure 2 are only optimal if there is an explicit agreement on how much each family at each income level is to spend on education. But a scheme in which the community agrees to pay some fraction of the cost of *each unit* of education purchased by the parents could lead to optimality in the absence of explicit agreement with each family. The optimal structure of these payments is not, however, one in which the community pays the same fraction of the per unit cost at all income levels, but rather it is one in which the fraction paid by the community varies inversely with income. In Figure 2, the community would pay fraction P_3B of the cost of each unit of education family 3 purchases, and a smaller fraction P_4B of the cost of each unit bought by family 4. It would pay none of the cost for "rich" family 5, and would pay the full cost for families 1 and 2.

A matching scheme such as this, with the community's share of the per unit costs varying inversely with income, can lead to that optimality in the provision of citizenship-oriented education which cannot be obtained simply by allowing parents to supplement equal-value state tuition certificates. If, on the other hand, the assumption that the community desires every child to attain some fixed minimum level of education is accepted, then efficiency requires unequal lump-sum public payments for different families. In either case the optimum community outlay varies inversely with income.

THE CHARACTERISTICS OF FOREIGNERS IN THE U.S. ECONOMICS PROFESSION

By HERBERT G. GRUBEL AND ANTHONY D. SCOTT*

While the theoretical aspects of the "brain drain," the migration of highly skilled people from the rest of the world to the United States, have been analyzed recently [2] [4] [5], very few reliable statistics on the actual magnitude of the problem are available. The unavailability of the empirical information is unfortunate because as a result we cannot answer the question whether the public concern over the brain drain reflects a new trend or merely a new awareness of a flow having a long history, nor derive insights into the drain from the less developed countries of the world, nor discover anything about the "quality" of the migrants, more specifically whether the "best" in some sense are drawn to the United States.

In this paper we have tried to provide quantitative information relevant to some of these issues by analyzing the characteristics of foreigners in the U.S. economics profession. The study has become feasible through the 1964 National Science Foundation project of registering the U.S. stock of scientific and technical personnel, which recorded the life and professional histories of American natural and social scientists through surveys conducted in cooperation with professional organizations.¹

Our analysis of the economics profession is useful even in the context of the broader question of the "brain drain" involving many other professions because economics is a science in which the transfer of foreign skills is probably about "average." On the one hand, foreign training in economics is not as readily transferable and useful in the United States as is the training of theoretical physicists. On the other hand, the tools of economic analysis are probably more uniform be-

*The authors are associate professor of finance at the University of Pennsylvania and professor of economics at the University of British Columbia, respectively. This paper was written while both authors were at the University of Chicago and it is part of a larger study concerned with the international migration of highly trained people financed by the Rockefeller Foundation and directed by Harry G. Johnson. We thank Harry G. Johnson for his intellectual and financial support and Milton Levine, Study Director of the National Register of Scientific and Technical Personnel Studies Group, National Science Foundation, for making available the data used in this study. We acknowledge gratefully comments by Zvi Griliches, J. G. Gurley, A. E. Rees and G. J. Stigler made on an earlier version of this paper.

¹The technical details of how the survey was conducted, the response rate, etc., are set forth in [1], to which the interested reader is referred.

tween nations than is the specific knowledge of lawyers or historians. Also, economics is not a licensed profession, which makes it easier for economists to practice in a foreign country than, for instance, medical doctors and lawyers.²

Before turning to the presentation and analysis of our findings it is necessary to discuss two characteristics of the data. First, as is common experience in survey data, some respondents failed to answer some of the questions. Consequently, the sum of all observations in each of the categories discussed often fails to be as large as the total sample. Under all income classification schemes, for example, somewhere between 5 and 10 per cent of the members in each class failed to report income statistics or had no income at all. We have simply disregarded these observations in our compilations of median incomes and deciles, a procedure biasing the computed averages in an unknown direction. The unknown bias does not, however, impair the usefulness of our statistics, since we are primarily interested in comparisons between U.S.-born and foreign-born economists and there is no reason to believe that the share of nonrespondents or zero-income earners is greater in one group than in the other.

Second, we had separate information on professional salaries and on gross professional income, but decided to use only gross professional income in our analysis because the use of both would have unduly complicated the presentation of the information without adding substantially to the insights attainable by the statistic we used. Gross professional income was considered to be a more relevant measure of professional success than basic salary since the earnings from consulting, royalties, and other honorariums included in the former are an important part of many economists' incomes.

I. Characteristics of Foreign- and U.S.-born Economists

Table 1 was compiled from the total sample and compares the characteristics of the foreign-born and the U.S.-born. As can be seen (from columns 1 and 3 giving the absolute number, column 5 the percentage), nearly 12 per cent of U.S. economists were born abroad. However, this percentage differs for the various age-groups (see column 5). The foreign-born are relatively most numerous among the oldest age-groups, are the smallest proportions among the very young and those who are now between the ages of 50 and 60, while their share in the age-group of 30 to 45 is in between these two extremes.

² A study concerned with professional migration to and from Canada found that according to the 1961 census the foreign-born postwar immigrants represent 25.2 per cent of engineers, 18.5 per cent of economists, 12.6 per cent of health professions and only 3 per cent of the law profession now working in Canada. These data are from [3, Table 21, p. 63].

| 8 | All Other | | | 9 |

An interesting feature of these statistics is that the lowest share of foreigners occurs in the age group of people who were born during or shortly after World War I, and who were likely to have been attending institutions of higher learning during the 1930s. During this period, on the one hand, Europe experienced the tyranny of the Hitler regime which encouraged emigration of older professionals, but the United States, on the other hand, was in the middle of the Great Depression which reduced incentives for immigration, perhaps more for students than for established professionals. One interpretation of the data is

TABLE 2—FOREIGN-BORN AS A PROPORTION OF TOTAL POPULATION AND OF ECONOMISTS

^a U.S. Census of 1960, Final Report PC(2)-2D.

^b Table 1.

that for people of university age at the time the latter factor seems to have been predominant over the former. Another explanation is that more foreigners than Americans of the relevant age groups were killed in World War II.

The secular decline in the proportion of foreign-born in the U.S. economics profession evidenced by Table 1 is put into perspective by the data assembled in Table 2. Throughout this period the share of foreign-born in the total population has fallen even more significantly (column 1) than that of foreign-born in the economics profession. Taking the proportion found in the total population as a basis (= 100) we have computed an index measuring the magnitude by which the role of foreign-born in the economics profession exceeds that in the total population. This measure shows an impressive and steady upward trend for the entire period except for the last age-group, which contains an insufficient number of observations for a meaningful interpretation. It suggests that the U.S. immigration has been selective, favoring the highly skilled or at least people capable of attaining high levels of skill.

Part B of Table 1 contains information about the level and source of scholastic degrees earned by U.S. economists. The most interesting feature of these data is that 75 per cent of the foreign-born received their high school education abroad, which means that probably no more than 25 per cent of them immigrated to the United States before the age of 18 or 19.

Section B.2 of Table 1 groups the economists according to the highest professional degree they have earned and indicates that the foreign born represent a greater share of the total the higher the degree. The next section of Table 1 reveals that fully 75 per cent of the foreign-born economists arrived in the United States before completion of their professional training abroad and enrolled in U.S. institutions of higher learning. Incorporating the information contained in Part D of Table 1 the following conclusion emerges about the extent to which the foreign born also received their education abroad: Of the 1330 foreign-born, 990 have foreign high school diplomas, 332 have a foreign second-highest degree, 317 have foreign highest degree.

The information about degrees also reveals that a very small proportion of U.S.-born economists received some part of their training abroad. The foreign highest degree most frequently obtained by U.S.-born economists is the Ph.D., of which there are in our data 46, representing 1 per cent of all Ph.D.'s held by U.S.-born economists. Part D of Table 1 shows the extent to which U.S. economists have obtained foreign degrees other than their highest. Interesting is Class 7 which shows that 39 Americans hold a foreign degree supplementing their otherwise complete U.S. education. Of these 39 about 72 per cent, 28, count the Ph.D. as their highest degree.

Section C.1 of Table 1 reveals that the foreign born are employed in relatively greater numbers by universities, state and local government, and nonprofit organizations and are relatively under-represented in industry, self-employment, consulting and the federal government. This pattern of concentration is not surprising if we remember that academia and sometimes also the civil service have been the traditional roads for advancement of members of minority groups in many societies, since in these fields objectively measurable output and examination performance are most important for success, and language and citizenship barriers are often the least restrictive.

The interpretation of income statistics in part C.3 of Table 1 must be handled with care because the two groups under examination differ with respect to many characteristics such as employment and age, all of which tend to influence professional incomes. We turn to a closer analysis of income data in Section III below.

Note: "—" means less than .5 per cent.

II. Countries of Foreign Birth and Training

In Table 3 we present an analysis of the shares of foreign born supplied by individual countries and continents. Especially noticeable, though not surprising, are the large numbers of American economists born in Western Europe, and in Germany, Austria, and the United Kingdom especially. There are more German-born economists in the United States than there are foreigners born in any of the continents other than Europe.

However, these absolute figures are not particularly meaningful and

comparisons of the importance of individual countries as well as estimates of losses from the "brain drain" require adjustments of the raw data to some common base. One adjustment factor widely used in studies of this nature, population abroad, does not appear to be useful in our context, since the level of industrialization, historic tradition in economics and other matters are the more important determinants of demand for and supply of economists. The computation of an index of adjustment incorporating these demand and supply factors requires data not now available and could not be handled in the framework of our study.

In Table 4 we have concentrated our analysis on the characteristics of economists who are both foreign born and foreign trained, focusing on holders of the Ph.D. from the major countries of Western Europe and Canada. The greatest proportion of Germans earned the Ph.D. degree in the decade of the 1920s, implying that they left Germany as young professionals during the Hitler years and that they have been expelled rather than "drained." There is a relatively large number of British, Benelux, German, Austrian, and Canadian economists who earned their degrees in the 1950s and now work in the United States. While these data could be interpreted as evidence of a "brain drain," it is quite possible that many of these men are in the United States for a period of postdoctoral training, planning to return home ultimately.

III. *Ph.D.'s in Academic Employment*

Of the 4,865 Ph. D.'s in economics for whom we have information about their place of birth and present employment, 70.5 per cent hold academic positions. We have chosen this group of most highly trained economists, all in the same type of employment, to investigate more closely the relationship between income and the country of professional training.

Such an analysis can serve two purposes. First, it serves to reveal whether the United States is attracting the "best" people, who we assume to be those who receive the highest pay for their professional services. If the United State really attracts the best foreign economists, then their incomes should be above the average of all U.S. economists since, assuming abilities to be distributed equally throughout the world, the foreigners are competitive in terms of ability only with the best of the American group. Two objections can be raised against the validity of this empirical proposition. First, foreigners may often be attracted to the United States by salaries which appear high in comparison with their domestic ones but are actually low given the U.S. scale and their ranking in ability. Second, foreigners may be very able but have training inferior to that of their U.S. colleagues. While both of

these objections may be considered valid for the period immediately following the individual's first arrival, they lose their validity later on, as the forces of the market tend to equalize pay for equal productivity and the foreigners make up for their deficient training through study and experience.

For our empirical test we have separated our data of 3,443 observations into four groups according to countries of birth and Ph.D.: (1) U.S.-born and U.S. Ph.D. (2,870); (2) U.S.-born and foreign Ph.D. (45); (3) foreign-born and U.S. Ph.D. (416); (4) foreign-born and foreign Ph.D. (112), and computed median incomes for each decade of birth for each of the four groups. The resultant earnings-age profiles have been plotted in Figure 1. For the middle decades a rather clear picture emerges: the U.S.-born and U.S. Ph.D. group's earnings are higher than those of U.S.-born and foreign Ph.D. group, which in turn exceed those of the foreign-born and foreign Ph.D. holders. The fourth earnings profile, that of the foreign-born with a U.S. Ph.D., behaves rather differently, exceeding the U.S.-born and U.S. Ph.D. in the oldest age groups but falling behind consistently in the following decades.³

Albert Rees has suggested to us the use of an index which, by giving proper weights to the number of observations in each age-income cohort, allows comparison of the four categories in a more direct fashion than does the graph. The index was computed by expressing the income of each age cohort as a per cent of the U.S. income at the same age, multiplying it by the number of observations in the cohort of the respective group, adding these numbers and dividing by the total number of observations in the respective group.⁴ According to this measure, the incomes of the four categories are as follows:

| | |
|--------------------------------|--------|
| U.S.-born and U.S. Ph.D. | = 100 |
| U.S.-born and foreign Ph.D. | = 95.5 |
| Foreign-born and U.S. Ph.D. | = 94.9 |
| Foreign-born and foreign Ph.D. | = 91.5 |

³ We need to point out that the numbers of observations in the 1885 and 1935 birth-group figures are rather small, suggesting that the results are meaningful only for the middle decades. We did not employ tests of statistical significance here since we are dealing with a full population, not a sample. Median incomes are as we report them, additional observations do not exist. Measurement error is the only source of random variation and we have no way of determining the variance due to this source.

⁴ The formula for the computation is:

$$I = \sum_{i=1}^k \left(\frac{Y_i}{YUS_i} \right) \cdot n_i \cdot 100 / \sum_{i=1}^k n_i$$

where I is the index, YUS_i is the income of U.S. born—U.S. Ph.D. cohort, Y_i is the income in the age cohort of the group for which the index is computed, n_i is the number of observations in the cohort and k is the number of cohorts in the group.

FIGURE 1. ECONOMISTS WITH PH.D. IN ACADEMIC EMPLOYMENT: INCOME-AGE PROFILES OF GROUPS DIFFERENTIATED BY COUNTRIES OF BIRTH AND TRAINING

On the basis of these findings it does not appear that the United States is attracting primarily the "best" economists from foreign countries. Also, the great melting-pot hypothesis according to which a person's place of birth has no influence on his earnings after he has been in the United States for a certain length of time does not seem to be supported by these data.

Several explanations of the income differences can be advanced, none of which, however, were we able to test any further. First, even though there is a world market for the best and the United States pays the highest salaries, other countries have nonpecuniary methods of compensating and holding their best, such as giving them prestige, power, and admiration through asking for counsel in public affairs, making them directors of institutes and bestowing official honors upon them. Second, many of the immigrants to the United States were not

primarily attracted by higher salaries, but fled undesirable social and political conditions in their native countries. These motives tend to work on all people of a professional group, regardless of their abilities. Third, there may be an element of discrimination in the hiring and promoting of foreigners even by employers such as universities and colleges, which are alleged to have very cosmopolitan views on such matters. Fourth, it is possible that economists with a worldwide reputation are primarily theorists, statisticians, and mathematical economists, while those of great capacity in applied work are both less well known abroad and (by reason of their vested interest in knowledge of local institutions and situations) less mobile. If this is true, market forces would tend to draw mainly theorists and mathematicians, etc., to the United States. This situation, in turn, would explain the lower gross incomes of foreign-born economists only if it is true that "applied" economists tend to receive higher gross incomes than academic theorists. Because *gross* incomes include consultation fees, research fees, etc. from government and industry, it is not implausible that the "market" *has* drawn the best foreign economists, but only those with a theoretical specialization.

We produced an income-index like the one just discussed for groups of economists classified by the countries which granted the Ph.D.'s. The results are based on relatively few observations (see line 1 of Table 4), and should be interpreted with caution. However, they do present an interesting ranking of the value of Ph.D.'s granted by some countries.

| <i>Birth</i> | <i>Ph.D.</i> | <i>Index of Income</i> |
|---------------|----------------|------------------------|
| United States | United States | 100 |
| Foreign | United Kingdom | 102.1 |
| United States | United Kingdom | 99.7 |
| Foreign | Canada | 95.8 |
| Foreign | Austria | 93.8 |
| Foreign | Germany | 89.9 |
| Foreign | Hungary | 68.1 |

Second, the analysis of Ph.D.'s in academic employment is relevant to the question whether the United States retains the "best" of the foreign students who have come to this country for training.

This proposition can be tested in the same way as was the previous one: The average incomes of the foreign-born with foreign secondary education but a U.S. Ph.D. should exceed the average incomes of those with a U.S. background throughout. We have grouped the foreign-born into the following four geographical areas of their high school: Canada, Western Europe, Asia, and All Other (in which Eastern Europe

Note: Numbers in parenthesis represent number of observations.

FIGURE 2. ECONOMISTS WITH PH.D. IN ACADEMIC EMPLOYMENT: INCOME-AGE PROFILES OF FOREIGN BORN U.S. PH.D., GROUPED BY COUNTRY OF HIGH SCHOOL, PLUS ALL U.S. BACKGROUND

predominates). For comparison we have also included the group of foreign-born with a U.S. high school education and a U.S. Ph.D. As can be seen from Figure 2, the income-age profiles of the Asian and "All Other" high school groups is considerably below the profile for the U.S. born and trained. On the other hand, people of all ages with a Canadian high school and those foreign born with a U.S. high school have incomes above their American contemporaries, and West European high school graduates have higher incomes than Americans during two of the decades. The numbers of observations in practically all

of the categories are quite large so that the figures shown can be treated with some confidence.

The computed index provides the following summary results:

| <i>Birth</i> | <i>High School</i> | <i>Ph.D.</i> | <i>Index</i> |
|---------------|--------------------|---------------|--------------|
| United States | United States | United States | 100 |
| Foreign | United States | United States | 111.8 |
| Foreign | Western Europe | United States | 102.8 |
| Foreign | Canadian | United States | 117.1 |
| Foreign | All Other | United States | 90.0 |
| Foreign | Asian | United States | 79.3 |

These computations suggest that the "quality" of Ph.D. holders of foreign birth and with a foreign high school degree is above that for U.S.-born and U.S. high school individuals for two geographical areas having a great cultural affinity to the United States and for which discrimination is likely to be smallest. The characteristics of the foreign-born with U.S. high school may be the result of well-known sociological and psychological factors common to minority groups. As for the low incomes of high school graduates from Asia and "All Other" (mostly Eastern Europe), we would suggest that they reflect discrimination rather than lower "quality," though we have no way of proving this proposition.

IV. *Summary and Conclusions*

Our analysis of the American economics profession in 1964 has revealed that the proportion of foreign-born is 12 per cent, which is about twice as high as that for the U.S. population in general. One quarter of the foreign-born arrived in the United States before high school completion, 75 per cent before acquisition of their professional degree.

Analysis by age-groups reveals that the foreign-born are a smaller proportion of the total the younger the group. But the proportion of foreign born in the economics profession is 1.1 times that for the population as a whole for the oldest age-group and is larger the younger the group. Breakdown of the foreign born by countries of origin shows that an overwhelmingly large proportion has come from Western Europe and other developed parts of the world, and only 18 per cent from Asia and Africa. Before being able to draw any conclusions about the "brain drain" problem from less developed countries in general, these data have to be put in relation to supply statistics; moreover, the economics profession may reflect only inadequately the developments in other sciences and professions.

According to the data, foreign-educated Ph.D.'s in academic em-

ployment have below-average incomes. One interpretation of this finding is that the United States does not attract the "best" economists from foreign countries, though discrimination against foreigners can also explain at least part of the income differences. The data reveal that economists with Western European and Canadian high school training who obtain U.S. Ph.D.'s and stay on at U.S. universities earn a higher income on the average than economists who were born and trained in the United States.

ON THE QUESTION OF OPERATIONALISM

*A Review Article*¹

By BEN B. SELIGMAN*

I

It is now a cliché, and no longer an accurate one at that, to describe Paul A. Samuelson as the *wunderkind* of American economics. It is not accurate because Samuelson is now past the half-century mark; yet he has been producing professional papers and articles as well as popular columns for sundry newspapers here and abroad (not to speak of the frequent revisions of his introductory text) in such profusion that we are apt to think of him as an elder statesman. But when the time sequence is placed into proper focus one must concede that the Samuelson corpus represents an extraordinarily sustained performance. Although Samuelson does not discount "late bloomers" in economics (*vide* his article on Abba Lerner as a case in point [13]), Samuelson himself illustrates the Schumpeterian dictum—a preanalytic vision of the economic process developed early in life and then carried through in an endless relation of give-and-take between empirical and theoretical work. For Samuelson this has meant the creation of a "grand neoclassical synthesis" combining modern national income analysis with the classical verities enunciated by the founding fathers.

This central view pervades the present collection of papers, whose 1,813 pages of text span the years 1937 to 1964. Its two large volumes, containing 129 articles, comments, lectures, and statements, include virtually all of Samuelson's contribution to modern economic theory, except, of course, the *Foundations of Economic Analysis* and *Linear Programming and Economic Analysis* (the latter authored jointly with Robert Dorfman and Robert Solow). One finds here the well-known articles on revealed preference, the transfer problem, factor price equalization, the pure theory of public expenditure, and the essays on Ricardian and Marxian economics. Included also are some fifteen pieces on purely mathematical topics, as well as the famous discussions of the multiplier, acceleration principle, and income determination. Some articles are published for the first time, known up to now to only an inner circle who were privileged to read them in manuscript; others have been resurrected from generally inaccessible books of essays, dedicated to professors on the verge of retirement, and from other obscure places. The latter include items on the constancy of the marginal utility of income; market mechanisms and max-

*The author is professor of economics and director, Labor Relations and Research Center, University of Massachusetts. He wishes to express his thanks to Professor Stanley Young for his comments and suggestions.

imization; the evaluation of real national income; probability and attempts to measure utility; a neoclassical reformulation of modern fiscal policy rules and principles; substitutability in open Leontief models; linear programming and economic theory; recent monetary controversies; intertemporal price equilibrium; the structure of a minimum equilibrium system; the 1961 Stamp Memorial lecture; a memorandum for the Canadian Royal Commission on Banking and Finance; and the 1962 Wicksell lectures. It is all quite a heady feast.

The task of putting the papers together was undertaken by Joseph Stiglitz, a graduate student, who has done a commendable job of organization. Several of the articles have postscripts redefining Samuelson's present position on the question at issue. Others are essentially predecessors of the *Foundations* or *Linear Programming*. (Curiously, two articles from *Econometrica*, published in 1941 and 1942, which were later incorporated in the *Foundations*, are also reprinted. One might ask whether the editor did not really gild the lily at this point!) The arrangement, which is topical rather than chronological, provides for five "books": (1) pure theory: consumer's behavior and capital theory (including the papers on Ricardo and Marx); (2) mathematical economics, linear programming, comparative statics and dynamics, and equilibrium systems; (3) trade, welfare economics, and income determination; (4) the theory of public expenditures, fiscal and monetary policy, and political philosophy; and (5) doctrinal history and methodology. Merely listing the categories is sufficient to underscore the broad scope and depth of the Samuelson *opera*. These in many ways represent the essence of contemporary economics; their significance stems not only from the mirror image they present of what has gone on in economics from 1937 to 1964, but also from the enormous impact that Samuelson has had on the way in which economists now think.

II

It would be only fair to indicate my own biases, which are those of an institutionalist who, contrary to popular opinion on institutionalists, happens to have a rather high regard for theory (after Keynes, who would dare denigrate theory?). But as I have indicated elsewhere, model building as a mode of theorizing needs to provide insights into economics as a *social* science, thereby providing materials for a more general theory of human behavior. I assume that goods and services are not only commodities and performances, but are significantly related to the human actors who control them and that the relationships between such actors are also economic. Yet such relationships may be infused and even dominated by other, noneconomic considerations, so that rationality and self-interest are not always the prime movers in human behavior. In fact, the noneconomic may provide parameters for the economic; insofar as this may be the case, many of the models of the economist need rather broad amplification.

I further feel strongly that a theory needs to be viewed not only in its own terms, but functionally as well, that it is the responsibility of a commentator to uncover the meaning of a theory for the particular time to which it relates. This is perhaps the most difficult task of all, and particularly so for an approach that has been developed during one's own lifetime. Nevertheless, such

criteria, I think, must be applied to Samuelson's total contribution, which is doubtless an important milestone in the intellectual history of economics. Lasting judgments at such close range may be impossible to make, but since I feel that his work will be pondered by students of economics long after most of us are gone, it seems useful to try. Let us then start at the beginning.

The notion of revealed preference was an early Samuelson contribution that is finally being enshrined in the textbooks. (When this occurs danger signals ought to be raised, for often the original idea is then emptied of all subtlety, a fate suffered by many a major economist.) An evaluation of revealed preference at this juncture, however, requires an estimation of Samuelson's methodological approach, a task we shall attempt below. Obviously, any theory of consumer behavior is intended to provide foundations for the law of demand, and in addition, the more sophisticated versions, such as Samuelson's, seek to establish underpinnings for the logic of index numbers. In older formulations the specified utility function, with price given, defined utility as a function of the quantities purchased, so that a continuous, smooth curve was derived. From this one could construct indifference curves and explicate the nature of substitution and income effects. All this is now well known from the work of such writers as Slutsky and Hicks [8] [9] [14]. Stated as simply as possible, Slutsky, for example, held that the lower the price of a good relative to another, the more attractive it would be to a consumer. The ensuing substitution effect would lead to a negative slope in the demand curve of the affected good. But with a lower price, purchasing power was enhanced, leading to an income effect which could cause a shift in the choice of commodities. That is, substitution and income effects were interrelated.

The roots of this rather refined approach may be traced to the 19th century marginalists, Jules Dupuit and Heinrich Gossen [16]. Further contributions were made by Edgeworth while others drew refinements from the work of D. Bernoulli as well as the psychologists Weber and Fechner who thought that a unit of sensation (utility?) was proportional to the original stimulus. So far as the economists were concerned, all this was an attempt to define the shape of the consumer's utility curve. By Slutsky's time, at about World War I, it was evident that Occam's Razor was to be ruthlessly applied: a theory of consumer's behavior was to be evolved that would be free and independent of psychological lumber. The thrust was toward a general theory, but one that would presumably accord with reality.

Yet the ensuing explanation of consumer behavior remained troublesome. While generality might be supplied by the notions of continuity and smoothness (i.e., infinitely large numbers of combinations of goods were posited along the utility curve with continuous first and second order partial derivatives) the argument nevertheless failed to establish a congruence with reality. It was at this point that Samuelson's revealed preference hypothesis seemed to come to the rescue, for if the observed behavior of the consumer fulfilled the basic Samuelson premises then it would still be possible to derive indifference curves and a demand function. The postulates were that a consumer would buy more of a good if such an action would not affect the amount of other goods he could obtain, and that his choices were consistent as well as transitive. In es-

sence, Samuelson introduced the notion of finite differences so that the observing economist was not required to work with instantaneous rates of change.

The theory seemed persuasive enough, except that it assumed a constancy of buying experience that did not appear to accord with the notion of "congruence with reality." Moreover, if the "observed" consumer were an ideal type of representative man, then the extremes of behavior to be found in such an implicit distribution of actors might very well by their eccentricities upset the search for generality. Consequently, the rationality suggested by revealed preference can be quite restricted. And since the information the economist seeks can be gleaned only after preference is revealed, it could be difficult to locate a counterpart of the theory's logic in the hurly-burly of an actual market place. True enough, many economists accept Hicks' dictum that there is no need to consider whether or not the real consumer acts like the representative man. But if such considerations are indeed to be set to one side, the economist runs the risk of constructing "black boxes" that in the final analysis are otiose. For if demand theory is really to describe consumer behavior, then the request for congruence to reality is a valid one.

From another standpoint, it would seem reasonable that the observing economist would welcome a way of independently determining the order of preferences in advance of the choices that a consumer makes. Surely this would provide a framework for empirically establishing consistency [3]. Revealed preference, with a logic internal to itself, cannot supply such information, and, as a consequence, it becomes virtually impossible to obtain independent verification of the rules of consumer behavior. For in fact consumers may really believe that price alone makes a good desirable and make their choices accordingly, or the range of choices may be actually intransitive so that the ensuing inconsistencies may indeed obliterate the postulates of revealed preference. Economists may consider such behavior pathological, but then so much of human behavior is precisely pathological.

Furthermore, since revealed preference deals essentially with points, repeated observations over time are required in order to arrive at sensible statements regarding consumer behavior. This presumes that experience has no impact on behavior, a concept rather difficult to digest. Yet given enough observations of what the consumer does, it is argued, we can derive his indifference map: the question that arises is—do we not come right back to the continuity and smoothness assumptions? There are problems then in utility theory that remain unresolved: one is uncertain that a concern for the minutiae of consumer behavior—under what conditions is tea a substitute for coffee *vis-à-vis* a third good—really adds much to our understanding of what in fact does occur in the market. Perhaps more important, one is not really convinced that the sophisticated mathematics of modern theory really cuts away from psychological roots, for the underlying details of consumer behavior are psychological and sociological as well as economic.

Samuelson does acknowledge some of these difficulties, especially in his 1950 article on integrability (p. 75 ff.): here he speaks of irreversible lag effects, inconsistent preferences for small changes, and the influence of collective or family preferences as important sources of divergent behavior. The

theorist, it would seem, is confronted by a dilemma. Once such difficulties are recognized, the empirical verification that would validate a *behavioral* theory becomes moot. Behavior patterns that might supply evidence to confirm or disconfirm a theory must necessarily stem from a kind of metaeconomics. (The term is used here in a somewhat different sense than is found in Samuelson's Part VII where, for example, the famous "correspondence principle" is described as metaeconomic. Why the mutual relationships of static and dynamic systems form a transcending principle of analysis is not clear.) The appeal to metaeconomics supplies what G.P.E. Clarkson has called interpretive rules that establish consistency between consumer action and theoretical models [3, p. 96 ff.].

Such rules—transcending principles or "going beyond"—it would seem, offer the most promising techniques for evolving criteria of verification. An investigation of the *decision* to buy may throw more light on preferences than the mere observation of the *act* of buying, which is where revealed preference begins. Consequently, the latter's behavioral terms may or may not be indicated. Have not all the external conditioning elements in choice-making been brushed aside in revealed preference? Does it really tell us how choice is made? Such questions seemingly raise issues of no small interest. For not all goods are subjected to identical evaluation procedures by the consumer, and his expectations regarding price movements do exert some influence upon his behavior. As Jan Tinbergen once remarked in quite another context, many more parameters of conduct are necessary, "most of which have not yet been measured" [2, p. 9n]. Revealed preference appears to suffer, as do most other variants of the theory of consumer behavior, from such limitations. This entire branch of economics may be questioned on the ground that it avoids what Galbraith has called the diminishing urgency of consumption in an affluent society [4, p. 150]. The reduction of consumer desires to terms of preference excludes the possibility that present needs might be fully satisfied in the calculable future.

On the other hand, I do not imply by any means that practical statistical research is in any better condition. Interviewing techniques to probe the mind of the consumer are filled with snares and traps galore, while time series and cross sectional studies may either overlook significant variables or deal with so many elements that the whole apparatus collapses. Yet we have gleaned enough knowledge of consumer behavior from the work of Kuznets, Brady, Duesenberry, and others that it may be more fruitful to pursue their line of investigation. Schumpeter once remarked that a theory ought to be a program for research. Insofar as consumer behavior is concerned, it seems dubious that theories such as revealed preference will perform that function. Perhaps economic analysis, as Samuelson said in his 1961 A.E.A. presidential address (p. 1499 ff.), does not really have to trouble itself with the state of the real world. This may explain why so many of the models that theorists construct are virtuous for their own sake; yet their often unmanageable mathematical framework must be subjected to a metaeconomics if we are to have a useful social science.

III

Why has economics taken this turn? Here one must examine some methodological questions, an area to which Samuelson has made important contributions. A fundamental issue involves the uses of mathematics in economics. In a paper given at the 1951 meetings of the American Economic Association (p. 1751), Samuelson argued that no distinction should be drawn between mathematical and nonmathematical modes of discourse. While the latter employs literary forms, said Samuelson, it may be argued that mathematics is also a language. In fact, he insisted, mathematics is language.

Now, that would seem to be fudging the methodological issue with a bit of poetic license. Mathematics is mathematics, with its own operational rules and logic. It may have had its roots in language and practical usage, but as it flowered, mathematics necessarily had to transcend the limits of direct experience. That is as it should have been, otherwise we would not now possess so powerful a tool. We may teach mathematics by using language, but what other pedagogic device do we have? Those who think that mathematics can be taught with symbols alone, or those who think that economic discourse should be restricted to symbols, might try learning Swahili by the crash Berlitz method.

If economists assume the task of describing, summarizing, and explaining empirical reality, as Samuelson says they must, then the transformation of mathematics in economics from a tool into a fetish will not help. Mathematics may be faster and more convenient in handling deductive inferences than ordinary logic in literary form (p. 1759), but not all practitioners are as good as Samuelson. He may very well have to paraphrase Marx—"Je ne suis économiste mathématique!" Indeed, mathematics may have swept the field like an epidemic of measles, as Samuelson says elsewhere, but it can become quite a serious ailment: all too often the very qualitative elements that underpin differences in variables are ignored [5, p. 119]. Having made so strong a case for the mathematical mode, he must take some responsibility for all those lesser lights who now believe that a symbol is the best entrée into the inner circle of expertise. An illustration of the latter situation is a model offered some years ago by a young economist in which national product was described as a function of capital stock services, the rate of use of natural resources, employment, society's fund of knowledge, and the cultural milieu. Stated in literary form, the expressions made sense, but translated into symbols, the cultural milieu became U , presumably capable of being subjected to all the mathematical operations of the calculus. Surely this is carrying an analytical simile to ludicrous extremes. And it goes on all the time.

One supposes that an ability to manipulate symbols expertly gives an economist a feeling of psychological advantage over his confrères who are less expert (on occasion Samuelson is not above such ploys). But that does not mean that they can predict better than anyone else the direction in which the economy will move. One can quote no better authority on this point than Samuelson, who recently noted that as far back as 1961 some of our best model builders had proved beyond a scintilla of doubt that the international pay-

ments problem would be solved. Yet the high aggregate demand in 1966 did spill over into international markets, upsetting the expectations for a sufficiently large current-account surplus that would keep us in overall balance.

True enough, mathematical economists have suddenly discovered a welcome mat in the middle and upper echelons of corporations and in the corridors of Washington bureaus, but they still have to speak English. A case in point is Samuelson's task force paper on economic policy prepared for the incoming Kennedy Administration in 1960 (p. 1478). It is an excellent document, well-reasoned and carefully delineating the goals, economic targets, and boundaries within which the new President would have to function. It didn't take much knowledge of mathematics to write that paper: its modern Neo-Keynesian policy formulations are clearly stated in pellucid English. Perhaps this merely illustrates the high skill and adroitness that Samuelson displays in literary as well as mathematical forms of discourse.

In any case, the mathematically oriented have their present triumph, and future historians may accord to Samuelson a fair share of the credit. But the victory is not entirely costless, since the current fashion stems in many ways from the apparent ease that it lends toward achieving full-fledged professional status. Few students are willing to undertake the task of dealing directly with empirical materials: nor do many arise before dawn to read Locke and Hume on futurity as, say, did John R. Commons. Having acquired a facility with algebra and calculus, it seems easier to construct a model and enter upon an academic career. Unfortunately, the issue of relevance is oftentimes cast aside. Let us be clear about the matter: mathematics can be a good tool in economics and a useful one in checking theoretical hunches. It gets closest to economics when it can deal with data, as say in econometrics, operations research, or input-output analysis. And there are areas—labor economics for one (which does deal with the behavior of the largest part of the population)—where mathematically based theory has but limited usefulness, despite recent efforts in the literature to expand its application. For man is what he is—changeable, irrational, and unpredictable.

IV

From a philosophic standpoint, one suspects that Samuelson would justify his reliance on the mathematical method by an appeal to that variant of positivism he calls operationalism. The latter suggests that every science must issue in a deductive system in which all observed events stem from structural laws involving relatively simple relations. Unfortunately, there is little outside the *Foundations of Economic Analysis* that one can draw upon to summarize Samuelson's philosophic views. In that *magnum opus* he contended that economics must be concerned only with operationally meaningful propositions, i.e., with statements capable of being refuted. This suggests that a concept must be defined in terms of its implicit operations, that a meaningful statement is one in which the operators can supply an answer. Yet that is not the sole method for conducting investigations in economics, or in other social sciences for that matter. There may be intuitive extensions into untrodden ter-

ritory that do not immediately yield operational propositions [11]. Indeed, it would appear that a good deal of scientific work began this way. Moreover, a purely operational approach unsupplemented by transcending data can stir up enormous difficulties. To employ a sociological illustration, the operationalist may believe that the causal relationship between poor housing and delinquency necessitates an improvement in housing as *the* way of reducing delinquency. The sad fact is that it does nothing of the kind.

More specifically, the reservations expressed here on operationalism are supported by D. E. Gordon's criticism in his review of Samuelson's *Foundations*. (*Quarterly Journal of Economics*, May 1955.) Samuelson's response is not fully convincing (p. 1767). Gordon had tellingly argued that Samuelson failed to supplement his principles of maximization and dynamic stability with a demonstration that the specified function would not shift unpredictably; that such shifts in the functions were left unexplained; that observed values might be characteristic of a stable function yet not exhibit a stable equilibrium; and that static conclusions do not always require the correspondence principle, that is, may not necessarily be rooted in dynamic conditions. Similarly, Nicholas Georgescu-Roegen [5, p. 59] speaks of qualitative residuals in a preference map stemming from the contrast of alternative choices of two goods and some admixture of such goods. In fact, the latter might be utterly distasteful thereby upsetting the presumption of proportionality involved in preference theory. But how the latter would be disturbed and the direction of its movement can be established only by a factual investigation, by requiring an appeal to a system of metaeconomics. Or what account would an operationalist take of the impact of new commodities on consumer behavior? Again Georgescu-Roegen says, a change in the character of goods does imply a rearrangement of both production patterns and consumer behavior, a factor not easily incorporated in the operational models thus far offered [5, p. 66].

These difficulties issue from the belief that economics has no need to consider questions that might involve value systems or qualitative elements. Many economists believe, neoclassical synthesizers included, that it is entirely possible to create a "science" that abstracts from all human goals. They believe that the semantic significance of knowledge necessarily consigns issues of values or statements about qualitative reactions to the realm of the senseless. A neutral perception of experience is offered, thereby denying that economics might be concerned with matters of values. In effect, there has developed a refusal to concern oneself with any implications other than those specified by a highly restricted model, with the consequence that economists become involved with technique for its own sake. The habit becomes too deeply ingrained to permit any consideration of the metaphysics of purpose.

The central fact in the contemporary world is an evolving, changing industrialism and within that state of immanence the major questions are those that explore man's role in it. We cannot take as given the institutional framework, since it is precisely that which undergoes change and which needs to be examined. Few theoretical economists have been concerned with the process of *becoming* industrialized or with its consequences: such issues are usually set aside by the rule of *ceteris paribus* under which all facts not immediately rel-

evant to theory are either set aside or dismissed. Granted that a theoretical model seeks to introduce order into the bewildering variety of variables and parameters and granted that an effort is sometimes made to relax restrictive assumptions; nevertheless, there remain numerous variables that never enter the particular model's equations. How often is it that a theoretical truth requires modification by unconsidered facts, facts which at first glance may not suit the theorist's pattern? At this point, the economist ought to display the angle of vision which permits him to look at society in the round. He needs to be that economist *cum* sociologist who disproves Schumpeter's *bon mot* that sociology is the proper occupation of a tired economist.

The operationalist approach suggests an imitation of the physical sciences and presumes therefore an ability to produce positive propositions. But why should we always imitate the physical sciences? They function, it would seem, on a different level of discourse and we economists ought not feel so guilt-ridden because we then cannot secure the same payoff. Naturally, economists borrow some of the methodology of the physical sciences and their standards of investigation. One does not depreciate such transactions, of course, but let us not suppose that we can duplicate the precision of their results. Society is a highly complex affair, and its components are not so closely and delicately knit that the slightest disturbance will immediately send convolutions gyrating in explosive fashion throughout the whole structure. A good many of the seams that hold us together are rather loosely sewn: there is much give and play and a change in one sector does not always transmit shock waves to the others. Institutional growth and selection are also loose: perhaps this explains the survival of a good many atavistic traits. The attempted application of the methods of physics to society is a facile escape from the complexities of our social condition. While we need to know what men do, we also need to know the aetiology of their actions, their motivations, their history. Albert Einstein was once asked, "If we have discovered the structure of the atom, why haven't we found a political means to keep the atom from destroying us?" He replied with characteristic wisdom, "It's quite simple. Politics is more difficult than physics." Not all the attributes of the universe can be reduced to space, motion, and mathematics.

It can be argued, therefore, that economic behavior is not quite analogous to physical behavior; to compare one with the other is to commit a serious logical error, for consciousness and the explication of meaning appear in the acts of humans that are not discernible in the movements of models. For the economist this would presuppose a wish to explore *interpretations* of economic actions in a manner that would expose root causes as well as shifts in interrelations. Generally described as the phenomenological approach, this method appears as one well worth the attention of economists.

As a philosophy, phenomenology is by no means an easy one to digest; moreover, the term itself is subject to numerous interpretations. Literally, a theory of phenomena, it may refer to an experienced object which represents some deeper reality that confronts us. Without exploring the roots of the concept in Kant, Hegel, Heidegger or Sartre at this time, we may note that phenomenological philosophers today generally address themselves to "subjec-

tive" descriptions in which human considerations are primary. Actions can be understood by applying a generalized principle of connectibility; it then becomes quite possible to derive general statements about economic or social behavior. Hence, objective propositions are entirely feasible, albeit intimately related to the subjectivity from which they stem. Objects, in other words, may be characterized by experience, and become actuality through phenomena generated by the subjective evaluation of facts and material goods. By no means does this reduce everything to mere experience, for theory can still display an independent persuasiveness. In economics, we do not deal directly with the relationships that contribute to the social fabric, but rather with "ideal" formulations—price levels, consumption, even index numbers—which nevertheless do not seriously violate facts.

Here then it may be possible to achieve what Niels Bohr had called complementarity [1], perhaps the most useful antidote to the self-assurance of operationalism. Bohr had observed that when light interacted with material substances two contrasting results could be observed: on the one hand, there was refraction or similar wave-like behavior; on the other hand, light appeared to travel in packets of energy. It was possible to work out a single set of equations based on the idea of complementarity, which could account for both effects. Reality, therefore, could not be fully described solely in terms of one effect or the other: in fact, conceptions that seemed to be antagonistic were reconcilable at a higher level of analysis as aspects of a single reality. Hence, operationalism is to be replaced, or at least modified, first, by probabilistic considerations, and second, by what has been called the ambiguity of complementarity. That is to say, theoretical science is not the only form of scientific knowledge, as, indeed, Georgescu-Roegen suggests, and economics cannot be limited solely to the realm of the measurable.

Essentially, economic phenomena may not be explained always by pure cause and effect, nor are they always linear; they are rather transactions, a phenomenon well understood by John R. Commons. Moreover, in these transactions there can be no certainty, a principle long established in physics, the science economists wish most to imitate. And, if Bohr is correct, then it may be possible to accept seemingly contradictory explanations of economic phenomena on the ground that the analysis of fact must be supplemented by understanding and comprehension. Those who seek to employ complementarity as a method in economics may wish to use behaviorist description not only to derive operational propositions but also as data to help mark off the margins of discourse. But it is important to note that an operational concept or definition does not insure that absolute clarity has been achieved. Georgescu-Roegen recently demonstrated that there are concepts that violate the principle of contradiction, that there are cases in which "B is both A and Non-A," that indifference may not necessarily occupy the ground between preference and nonpreference [5, p. 22 ff.]. It is in such situations that the idea of complementarity may be most helpful.

Some economists have, perhaps unconsciously, attempted to achieve a measure of complementarity. While it may be too early to judge their success, we may observe that they have sought to weave a web of operational analysis

into the tradition of amelioration established by Mill, Marshall, and Keynes. Samuelson may be classified as a leading practitioner of this difficult approach for, while he has insisted on verifiable theorems, he has conceded that the economist ought to be ready to offer policy proposals, which though reflecting value judgments, do not wander too far from accepted humanitarian standards. Unfortunately, some of the theoretical concepts have skirted close to the edge of emptiness; for example, when consumers' behavior is explained by preferences with the latter defined by observed behavior, the analysis threatens to become circular. The way out seems to be the assumption of a definite commitment by the consumer before a description of his state of mind is possible. This ordering then allows the observing economist to derive welfare propositions from single acts of choice. Yet even as Samuelson has observed, not much of great significance is forthcoming from all this legerdemain. The conclusion that more production of a good might be desirable, or that the same output could be obtained with less input, is admittedly not very striking.

Complementarity also reveals that economics is but one way of examining the totality of human behavior. Traditionally, economics has explored the areas of production and distribution. But goods and services are not merely commodities and performances; they are in a real sense the expressions of human actors who control them and who in turn are controlled by them. Moreover, the relationships which the actors establish between themselves are also economic. And it is the culture arising from these relationships, acting in reciprocal fashion, that determines the movement of society and the fate of man. How the dangers and rewards of existence are to be shared is established in the last analysis by these cultural forms. The material fact of scarcity may be present at the start, but human action makes the material fact a social pattern.

We suggest then that the immanent meaning of economic theory may be grasped by its relations to *praxis*. In this context, verbal meanings and practical goals are often antecedent to logical validity and analytical elegance. Further, if economics is a science of fact rooted in the human condition, it would be necessary to check theory against those events established at the level of connectibility. No simple correspondence should be expected, however, for economic facts are all too often squeezed through the grinder of political policy and social turmoil. But all too often the problem of relevance is ignored, for theory itself is a way of perceiving reality. Unless this perception is achieved, theory cannot perform its primary function—that of guiding empirical inquiry.

V

It is fascinating to watch Samuelson employ his technique, when the occasion demands it, to transcend the limits of his own preconceptions. Here one examines his brilliant dissection of the Friedman formula for model building (p. 1772). Samuelson once wrote to the present writer that it takes an analyst to answer an analyst, and though I am not sure that I would agree, he may understandably offer this piece as the prime exhibit in support of his contention. Professor Friedman, it will be recalled, argued in rather extreme fashion

that direct verification of an hypothesis is not an essential ingredient of a model, for if a prediction is not contradicted by events, then the initial set of assumptions is fully acceptable even though there may be no "congruence with reality." Samuelson's rebuttal is extraordinarily powerful, yet essentially a simple one, employing set theory to demonstrate that consequences are contained in antecedent theorizing, which in turn is implied by certain premises, or as Samuelson would say, minimal premises. By violating this sequence, the Friedman approach improperly admits invalid propositions into analytical discourse.

It is a pity the editor of these papers was unable to include the subsequent debate on this issue [10]. Some sharp words were addressed by Samuelson to his correspondents. (In the author's preface to the *Collected Scientific Papers* Samuelson hopes that he has mellowed over the years. He can be assured that such is not the case. For example, he suggests (p. 1762) that those who are uncomfortable with his sort of theory might prefer doctrinal history or labor economics. Since these happen to be my major areas of interest, I could not help but raise my eyebrows at such a quip; did its maker wish to place boundaries around his specialty, keeping out everyone else as a mere poacher?) In any case, the discussion in the *American Economic Review* drifted from the problem of unrealism in theory to the nature of theory itself, with Samuelson emphasizing a search for empirical regularities as a basis for theoretical foundations in economics. So far as this goes, I must opt for the Samuelson position. One cannot quarrel with his statement that the description of empirical regularities provides a basis for prediction or that explanation is a form of description. Yet in a social science such as economics we may still need a measure of looseness not envisaged in strictly operationalist formulations. Physicists have worked for a long time with concepts that were imprecise by present standards, and it is only recently that a "gene" has been "exactly" defined. There are areas of economic and social science that can be usefully explored by methods and concepts that do not completely partake of the Samuelson purview. To be sure, one must seek to improve and advance conceptual foundations; all one asks is a measure of tolerance from the operationalist, who does not yet, I think, have the last word.

Samuelson's versatility is illustrated by his work in some of the newer, more esoteric areas of economic research—game theory, input-output analysis, and linear programming. His contributions to linear programming are fundamental and now form part of the basic literature. On the other hand, he evidently has been less happy with game theory, founding his reservations on a reluctance to accept the notion that utilities are additive. A cardinal concept such as is implied in game theory is "usable," he has contended, only if there is an external measure proportional to the utilities of the players. The latter assumes that utilities can be specified on some scale of intervals, that is, to make them invariant via linear transformations. Samuelson's hesitation is expressed in the paper, "Probability and the Attempts to Measure Utility" (p. 117) which has an interesting postscript conceding the possibility of employing the utility concept in this manner, followed by a paper on the independence axiom which would allow for additive properties in certain cases (p. 137).

Nevertheless, linear programming appears to be the area that has captured Samuelson's attention, mainly, it would seem, because it does permit a numerical specification of the neoclassical synthesis that he has been advocating over the years. This in no way, of course, minimizes his frequent explorations of the interrelationships that game theory and input-output analysis patently exhibit with linear programming. But it is the latter that has been emphasized, most notably in "Market Mechanisms and Maximization" (p. 425), a paper originally prepared for the RAND Corporation and in "Linear Programming and Economic Theory" (p. 493).

One of the more significant propositions stemming from this work has been labelled the "Turnpike Theorem." It is one of those theoretical formulations that arouse marked interest because it has imbedded in it direct policy implications. A number of writers have offered subtle variants—R. Radner, L. W. McKenzie, M. Morishima [6, p. 104 ff.]. Samuelson's contribution is to be found in the paper on market mechanisms, as well as in one on capital accumulation (p. 287) and one on balanced growth written jointly with R. M. Solow (p. 248). These articles are to be supplemented by the discussion of *Linear Programming and Economic Analysis* in Chapter 12. In these papers—particularly the one co-authored by Solow—one finds mathematical demonstrations of the existence and uniqueness of a balanced growth path, the elements of proportionality of the factors involved, the stability of these proportions, and the suggestion that consumption levels are maintainable under the conditions of "turnpike" growth.

It will be recalled that the turnpike theorem, which theoretically specifies the fastest, most efficient path, has its roots in von Neumann's general equilibrium model of economic growth. The latter described an economy in which the production function exhibited fixed, linear homogeneous properties, where all outputs were inputs, where demand functions of the ordinary kind were excluded, and where all input factors were in limitless supply. The objective was to reveal a path describing a constant equilibrium rate of growth under conditions of perfect competition and zero profits. The equilibrium growth path then required money outlays on inputs to be greater than or at least equal to the value of outputs and the current inputs of any item to be less than or equal to the output of that item in the preceding period. As a consequence, only one such equilibrium rate could satisfy the uniqueness and existence conditions and there was a unique value for the rate of interest and the equilibrium rate of growth. Outputs in excess of those flowing from the equilibrium growth rate were deemed to be free goods. And competition insured that there could be only one such sustainable growth rate.

Consumption, in this original formulation, was not part of the model, so that the von Neumann case appeared as a special one within a more general framework. Essentially, as John R. Hicks has shown, the turnpike theorem is a statement about economic planning [7, p. 201 ff.]. It asks the significant question: what will production plans be, given the initial capital and the future flow of capital, that will enable an economy to reach some future target? Yet, various turnpike models, including Samuelson's, seem to display certain common features that do raise troublesome questions. For one thing, they ab-

stract from the organizational structure necessary to achieve the stated objective (theorists may take this as a "given," but I doubt that this is enough). Secondly, there seems to be no time horizon to which they are addressed, in almost all cases appealing to some vague precept "given enough time." Further, the assumption that surplus goods, i.e., goods in excess of that required for the equilibrium growth path, are noneconomic is much too facile; discarding such goods may place the growth path on a line that varies substantially from the optimum [7, p. 228 ff.].

The most serious problem, however, is the model's concentration on capital endowments. To be sure, Samuelson has been more aware of this problem than other writers, yet in most instances, the theorem in its various guises has explored the techniques that would maximize "final" capital. Hicks has described planning based on such motivations as stemming from a "war mentality." His characterization may be a harsh one, but the planning philosophy stemming from "turnpike" theorizing does suggest a "crash" technique; adopted by underdeveloped nations, it has had some unfortunate consequences. The paradigm, of course, is the debate over the pace of development that took place in the Soviet Union in the early 1920s. On the one hand, there were advocates of a kind of paced development to account for the output and demand patterns in agriculture and consumption; on the other, there were the devotees of a massive investment program that would achieve a rapid expansion of "heavy" capital goods [15]. The extraordinary burdens that the latter strategy imposed are well known. Reverting to the "turnpike" concept itself, it would appear that Hicks' evaluation is much to the point: the "turnpike" is simply one of several optimum paths and one ought to search for a model that allows for per capita consumption growth.

Samuelson, to no one's surprise, has already done so, though it appeared too late for inclusion in the present volumes [12]. His new theorem suggests that, *given enough time*, a balanced turnpike growth path would provide maximum per capita consumption. That indeed is the rub—what is "enough time"? Given "enough time" even the Soviets, with their unbalanced growth pattern, may evolve a high-consumption economy. Would 50 years be enough time? How, in the meantime, would the projected growth path be influenced, say, by technical change? And what influences would uncertainties generated by time lags or wage rate movements exert on the optimum growth path? These would appear to be but a few of the practical issues from which the theory abstracts.

VI

If I have given the impression that the first two "books," as well as parts of the third, are rather rough going, that indeed was my intention. At times the high powered symbols are handled after the fashion of those British mathematicians who blithely say: "It can be shown that . . ." Yet no doubt the feast is rich enough to whet the intellectual appetites of economists for years to come. The last two books—on public policy and doctrinal history—are lighter fare, though no less challenging. The reader will find here perceptive comments on fiscal and monetary policy, several excellent essays on famous economists

(Keynes, Schumpeter, Hotelling, Robertson), and the insightful Wicksell lecture on the state of the American economy. Yet some are not so good: if Beethoven had his *Battle Symphony*, Samuelson may be forgiven his Stamp Memorial Lecture. Aside from a memorable last sentence ("... what do they know of economics, who political economy do not know?"), the lecture rambles painfully and succeeds only in specifying a number of economic issues then current without saying much about them.

On the other hand, if I were to choose the best of the group, the accolade would go to the statement prepared for the Canadian Royal Commission on Banking and Finance in 1962 (p. 1361 ff.). While agreeing that money and credit policies have enormous influence on the course of an economy, Samuelson makes it clear that monetary policy is not the sole mechanism for influencing aggregate behavior. He rejects the notion that adjustments in the supply of money—say 3 per cent a year—would be sufficient to provide the automaticity that some economists believe to be desirable, for "... choices have to be made pragmatically in terms of the goodness or badness of behavior patterns that result from various kinds of discretionary action" (p. 1362). The implication that human action is subject to a decision-making process that is less than completely automatic is well taken. Hence, the attempt to prove a controlling causal proportionality between money supply and aggregate income cannot be convincing. The technical issues involved are so clearly stated that it seems difficult after Samuelson's discussion to defend the quantity theory of money in any of its versions. Says Samuelson tartly, "Optimal stabilization policy must vary with the probability pattern of the system to be stabilized, which makes it rather ridiculous to specify in advance for all times that some particular gadget like 3 per cent money-increase-per-year should be adhered to, in season and out of season" (p. 1376). The clarity of his distinctions between monetary and fiscal policy makes this essay one of the best didactic pieces in the collection.

I realize that there is much in these volumes on which I have not commented. To do so would extend an already lengthy review. The essays on Marx and Ricardo are powerful dissections of these systems from the standpoint of modern analysis; the early articles on the multiplier and acceleration remain viable analytical documents; the papers taken from various published symposia on the state of economic thinking are very good reading indeed; and the A.E.A. presidential address stands up surprisingly well, even after a third reading (although, I still do not believe that economists should work solely for each other's applause). What the papers in the last two "books" particularly illustrate, as they move toward greater and greater relevance, is that Samuelson's neoclassical synthesis is heavily weighted on the Keynesian side. They represent an elucidation and extension of the best of economic thinking of the last thirty years. It may be premature to put Samuelson into the pantheon of the greats, but there is no doubt that he is knocking on the door.

One final word and mild protest: the publishers have used a photo offset process to fit all sorts of formats onto a standard $5\frac{1}{2} \times 9$ page. The result is a random sequence of typography ranging from miniscule 4-point type to a font that appears gigantic by contrast. One's eyesight rebels against such

printing barbarities. Nevertheless, the material is there to be read and mulled over on long winter evenings.

Implicit Tax Rate Reductions with Growth, Progressive Taxes, Constant Progressivity, and a Fixed Public Share

The presence of progressive elements in the tax system implies that increases in per capita income will produce more than proportional increases in tax revenue. This well-known aspect of our tax system has been discussed most frequently, until recent years, in terms of contracyclical fiscal policy and "automatic stabilizers." More recently, with the widespread shift of interest to the question of economic growth, the effect of a progressive revenue structure is more likely to be discussed in terms of a persistent contractionary force during periods of rising income and output. The "full employment surplus" concept developed by the Council of Economic Advisers has been used to make this point.

More specifically, let us assume that the share of public sector spending in total spending is to remain constant over a period of sustained growth in total and per capita income. Then a tax system with progressive components will generate ever-rising full employment budget surpluses. If full employment is to be maintained under such circumstances, and if private consumption spending maintains its roughly constant share of disposable income, then private investment must continually rise as a share of total output,¹ tax rates must be periodically reduced, or progressive taxation must be abandoned.² Still more precisely, if planned private full employment saving and investment remain roughly equal over time, the pattern of periodic tax rate reduction must produce tax revenues proportional over time to national income, the required proportion being the desired share of public spending in income and output.

It is the purpose of this paper to state with rigor and precision the pattern of tax rate reductions which will meet these requirements. The question is approached in Part I by means of a theoretical model with highly restrictive assumptions, as indicated below. After the required pattern of tax rate reductions is established for the simple model, the results are generalized sufficiently to talk about the present situation of the United States. In Part II, the 1964-65 personal income tax cut is evaluated in the light of the

¹ This possibility perhaps implies falling interest rates, and/or accelerating technological advance, and an accelerating rate of growth. We shall sidestep all these knotty issues and related questions of liquidity traps, the interest elasticity of investment and the like by concentrating our attention on the tax reduction case. More simply, we may observe that balance-of-payments considerations rule out for the present any possibilities of the easy-money-tight-fiscal-high-investment policy mix.

² We shall sidestep the controversy over progressive taxation by restricting our attention to the case in which progressive taxes are retained. This appears to represent a long-standing consensus in the United States; in fact, political pressures are such that changes in the degree of progressivity are likely to be small in either direction. This observation lends further relevance to our model's concentration on the constant-progressivity (defined below) case.

theoretical analysis of Part I. Part III explores some further implications of the ideas discussed in Parts I and II.

I. *An Aggregate Tax Model*

Assume an economy with the following characteristics: (1) constant population, (2) steadily rising income and output per capita at rate z per year, (3) an unchanged distribution of income over time, (4) no taxes other than a progressive personal income tax, (5) government spending is a constant share of total expenditure, and (6) planned private saving and investment are equal at full employment so that (7) the appropriate behavior of aggregate tax revenues over time is to maintain the share of income given by the desired share of public sector spending in total output. The last assumption implies a continually balanced public budget.

In the model which follows, households (or tax-paying units) are arrayed by income from the lowest to highest; the resulting array may be described by the income function

$$(1) \quad y = f(x)$$

where y refers to an individual household's income and x to its place in the array. The i^{th} household, for example, has income $f(x_i)$. As explained above, the number of households, n , for the moment, is held constant. If we assume a continuous function (as we easily may with n large), aggregate income, Y , is seen to be

$$(2) \quad Y = \int_0^n f(x) dx$$

It also follows that aggregate income is rising at rate z if the income of the household occupying each position in the array is rising through time at rate z , and the distribution of income among households remains unchanged.

The income of the household occupying the i^{th} place in the array is then, at time t ,

$$(3) \quad y_t = e^{zt} f(x_i)$$

and aggregate income at time t is

$$(4) \quad Y_t = e^{zt} \int_0^n f(x) dx$$

Further, it is not strictly required that every household's income rise at rate z ; households may "switch places" as long as the occupant of place i has an income e^z times that of the occupant one period before.

Suppose now that the progressive income tax in question is of the form

$$(5) \quad r = ay^b$$

where r is the tax rate. This function, apparently first fitted to U.S. data in [1], gives a rather good fit to U.S. personal income tax data for 1962, as is

shown in Part II of this paper. This function has a number of useful properties; the tax amount per household, for example, is simply $y \cdot ay^b$ or ay^{b+1} . Aggregate tax revenue, T , is given by

$$(6) \quad T = a \int_0^n [f(x)]^{b+1} dx,$$

A further important property is the following: the elasticity of T with respect to Y (Y changing only via increases in y , distribution unchanged as above) is simply $b+1$.³

The tax is, of course, progressive if $b > 0$, proportional if $b = 0$. With a and b unchanged, T/Y rises through time if Y rises through time by means of rising per capita income.

Now consider the problem of keeping the share of national income paid in taxes constant through time while per capita income rises; and doing so in such a way as to keep the progressivity of the tax system unchanged.⁴ We have already shown that aggregate income is rising at rate z per year, while aggregate tax revenues are rising at rate $z(b+1)$ per year. Our problem, then, is to reduce tax rates steadily in such a way that tax revenues rise only at rate z per year. Referring to (6), we observe that this may be accomplished by steadily lowering the parameter a at rate zb per year.⁵ Each household's income after tax thus rises at rate z , so that the progressivity of the tax structure remains unchanged as required.⁶ This result is consistent with the observation that the parameter b is, after all, the "progressivity" parameter.

Aggregate tax revenues might also be maintained at a constant share of national income by steadily lowering the parameter b ; that is, diminishing the degree of progressivity through time. The appropriate time path for values of b is not as simple as is the case for a , but tax rates may be reduced (or increased) by changing b through time.

Our model may now be generalized in a number of ways. First, consider a tax system with proportional and progressive components. It will behave over time as our model suggests in that aggregate tax revenues will rise at a faster rate than national income, though less rapidly than in our model. Revenue proportionality through time is easily achieved by applying our

³ A formal proof is given in [1] or is available from the author. Briefly, aggregate income is rising at rate z per year, while tax revenues are rising at rate $z(b+1)$ per year. Thus $dT/dY \cdot Y/T$ is $b+1$. The cross-sectional tax-income elasticity is also the aggregate time series tax income elasticity. The result holds regardless of the form of the income distribution function, provided only that it remains unchanged over time.

⁴ By "keeping progressivity unchanged," we mean that the after-tax distribution of income among families does not change through time. Bear in mind that, by assumption, the distribution of before-tax income is also unchanged through time.

⁵ Since the whole expression (6) is linear in a and would otherwise be rising at rate $z(b+1)$, dropping a at rate zb reduces the rate at which (6) rises to $z \cdot 1 = z$.

⁶ By (3) and (5) the after-tax income of the i^{th} household (at time $t=0$) is $f(x_i) - a_0[f(x_i)]^{b+1}$. Its before-tax income, growing steadily at rate z , is (at time t) $y_t = e^{zt}f(x_i)$, and its after-tax income at time t (with the parameter a falling at rate bz from its initial value a_0) is $y_t = e^{zt}f(x_i) - a_0 e^{-bzt}[e^{zt}f(x_i)]^{b+1} = e^{zt}f(x_i) - a_0 e^{zt}[f(x_i)]^{b+1}$. This is simply e^{zt} times the initial after-tax income which is therefore growing at rate z .

results to the progressive components of the tax structure.⁷ Next, consider an economy in which both the number of taxpayer families and family income rise through time. The first factor tends to produce rising tax revenue in proportion to rising national income, while the second factor introduces the effect treated in our model. Again, revenue proportionality may be maintained as suggested in our model.

Cases in which the public sector grows at some rate other than z may again be readily handled; the tax parameter a (or b , if progressivity changes are desired) is simply lowered slower or faster than rate bz , depending on whether the desired public sector growth rate exceeds or falls short of z . Insofar as contracyclical fiscal policy is desired, rate reductions are accelerated in downswings, and delayed in upswings (subject, of course, to the usual forecasting and lag problems). Moreover, the a and b parameters may be varied in offsetting ways. Progressivity may be increased (by raising b) while tax rates in general are reduced (by more than compensating reductions in a). As we shall see, this appears to be the case with respect to the recent tax cut.

II. *The Federal Personal Income Tax in the United States*

The federal personal income tax in the United States may be approximated very closely by the function $t = ay^{b+1}$ where y refers to each taxpayer's adjusted gross income and t to his tax liability. As noted above, this function has already been fitted to U.S. data for 1953. I have calculated mean adjusted gross income and mean tax liability in 1962 for each of the 29 income classes reported in [2] by dividing the number of returns in each class into total adjusted gross income and total tax liability for the class (data reproduced in Appendix I). Regressing logarithms of mean tax liability on logarithms of mean adjusted gross income gives the following estimates of the a and $b+1$ parameters in the above tax function (standard errors in parentheses)⁸

$$(7) \quad \log t = -5.4034 + 1.3589 \log y \quad (r^2 = .9936) \\ (.04615) \quad (.02189)$$

The bottom two income classes (0-\$600 and \$600-1000) were omitted since the first has a zero tax liability (impossible with an exponential function) and the second yields negligible tax revenue. As the small standard errors

⁷ We ignore regressive elements since they are swamped quantitatively in the United States by the federal personal income tax. The reader may easily further generalize our model to cover tax systems with larger regressive components.

⁸ The standard error in this case must be qualified in that we are regressing mean taxes on mean incomes for each income group, and all measures of error apply to these means. Individual taxes are much more widely dispersed, but this dispersion is, in effect, removed by averaging. This qualification is of no particular moment when one deals, as we do, with aggregate tax revenues. It should not be inferred that the standard error of estimate for any individual's tax liability is as low as the standard error of estimate for each class mean.

indicate, estimates of both parameters are significantly $\neq 0$ by the ordinary t test.⁹

The fit is improved, and the estimate of the $b+1$ parameter raised, if the top four income classes are omitted, as follows:

$$(8) \quad \log t = -6.6011 + 1.4943 \log y \quad r^2 = .9996 \\ (.00424 \quad (.00715))$$

The parameter estimates are again (much more) significantly $\neq 0$ by the t test. Equation (8) compared to (7) indicates that the cross-section tax income elasticity declines in the very highest income classes. Actually, the rate structure climbs so steeply up to an income level of \$100,000 that rates in the highest brackets would have to exceed 100 per cent to maintain the pattern of rate increases found below the \$100,000 income level.

Adjusted gross income, to be sure, is not conceptually identical to personal income in the national income and product accounts. Transfer payments are omitted, capital gains are included, and tax-free interest payments (significant only in the high tax brackets) are omitted, to name only a few of the more obvious discrepancies. It is not easy to determine the extent to which our conclusions would be modified if good data on personal income and tax liability arrayed by the same income classes were available. There is the further complicating issue of capital gains (realized and unrealized). Realized gains are included in our adjusted gross income figures, whereas they would not be included in officially estimated aggregate personal income. One might argue that capital gains in part reflect reinvested corporate earnings so that they might properly be regarded to some extent as income. In any event, it is difficult to imagine that the parameter estimates would be drastically affected, especially the comparisons of parameters before and after the 1964-65 tax cuts discussed below.

The next question concerns the parameters of the income tax function after the 1964-65 rate reductions. I have approached this question by taking the 1962 mean adjusted gross income for each of the 29 classes and estimating for each class the mean tax liability which would result from the 1965 rates, with further adjustments for the removal of the dividends-received credit and the establishment of the minimum standard deduction.¹⁰ Other changes in the tax code appear to have little effect on the overall progressivity of the tax and were not considered in estimating 1965 taxes for each income level. The estimates are given in Appendix I.

⁹ Mishan and Dicks-Mireaux in [1] estimated the coefficients as

$$\log t = -2.49801 + 1.42483 \log y \quad (r^2 = .9983)$$

for 1953 taxes. Their result differs from ours principally in the estimate of a , a result not surprising, given the temporary Korean War 10 per cent rate increase still in effect in 1953. The subsequent reduction is reflected in the 1962 rates which were the same in 1962 as in 1954. Various deductions and exemptions had, of course, changed but rates in general had not. Dropping the 10 per cent rate increase (as was done in 1954) would affect a , not b .

¹⁰ More specifically, the application of 1965 rates to mean 1962 adjusted gross income for each income class involved the following steps: (1) for 1962 mean taxable income in each class, calculate the tax liability using both single and married taxpayer rates; (2) select the calculation which most closely approximates the 1962 reported mean tax liability, and calculate the

When estimated mean tax liabilities are regressed on mean incomes (again omitting the two bottom groups), parameter estimates are:

$$(9) \quad \log t = -6.2081 + 1.4174 \log y \quad (r^2 = .9914) \\ (.06737) \quad (.02644)$$

As before, the fit is improved and the estimate of $b+1$ raised if the top four income groups are omitted:

$$(10) \quad \log t = -7.6538 + 1.5809 \log y \quad (r^2 = .9986) \\ (.01468) \quad (.01330)$$

Again, a glance at the standard errors indicates the significance of the parameters.

We may now examine the tax cut in the light of our earlier analysis. As expected, the parameter a is reduced as we compare (7) and (9) or (8) and (10). The hypothesis that a did not change is easily rejected at the .01 significance level in both cases. It appears that a fell about 55 per cent (or, omitting the highest brackets, 65 per cent). If the rate reductions had been confined solely to this parameter, tax revenues from 1962 income would have fallen by about 55 per cent. Using our results of Part I, such a reduction would have absorbed the increase in revenues—over and above a constant proportion of national income—for a period of over 65 years. Actually the reduction in revenues (income held constant) was about 20 per cent; the reduction in a was in part offset by an increase in b . The tax reduction, therefore, disposed of the increase in revenues (beyond a growth proportional to national income) for about 20 years.

Now we consider the hypothesis that the parameter $b+1$ was increased by the 1964 legislation. If we omit the 4 highest income classes and compare (10) with (8), the increase in $b+1$ is significant at the .01 level by the t test. Comparing (9) with (7), the results are less certain. At the .01 level, the difference is not significant; one would have to adopt a significance level slightly above 10 per cent before the increase in $b+1$ would meet the test. We may conclude that the progressivity of the tax clearly increased for income levels up to \$100,000, a result partly explainable by the adoption of a minimum standard deduction and the elimination of the dividends-received credit. For the very highest income groups, the new tax rates remain strongly progressive, but one can give no clear-cut answer as to whether the tax function in that area is more or less progressive than before. We should also mention the probability that errors in estimating tax liabilities on the basis of the 1965 rates are largest in the highest income brackets.

percentage deviation; (3) use 1962 taxable income as the base for estimating the tax liability at 1965 rates (this implies the same deductions and exemptions except as noted below); (4) apply the 1962 single or married rate for each income class as determined by (2), and adjust by the same percentage deviation; (5) recalculate for each class, beginning with the lowest; apply an estimated minimum standard deduction; continue until the results do not differ from the previous method (in this case, the 4000–4500 income bracket); (6) in higher income returns, separately calculate the tax on capital gains, and the dividends-received credit.

III. *Summary and Further Implications*

The foregoing analysis has suggested that federal personal income tax revenues will rise about 1.4 per cent for every 1 per cent increase in income per taxpayer. In a world of continual full employment private saving-investment equality, full employment would require a rising government share in total spending, or periodic tax cuts. If a constant tax-income relation, and a constant degree of progressivity are desired, the indicated tax cut pattern, as noted above, is a reduction in a at the rate bz per annum. In a cyclical, balanced-budget-over-the-cycle world, tax cuts would have to average rate bz per annum, but could be integrated into the pattern of contra-cyclical fiscal policy by delaying rate reductions during upswings, and accelerating them during downswings. If there appears to be some chronic

APPENDIX

MEAN INCOME, AND MEAN TAX LIABILITIES FOR 1962
(ACTUAL) AND AT 1965 RATES (Estimated)

| Income Class | Mean Adjusted Gross Income | Mean Tax Liability 1962 Rates | Mean Tax Liability 1965 Rates |
|-------------------|-------------------------------|-------------------------------------|-------------------------------------|
| (1) | (2) | (3) | (4) |
| 0-600 | 326 | — | — |
| 600-1,000 | 798 | 14 | 8 |
| 1,000-1,500 | 1,241 | 52 | 30 |
| 1,500-2,000 | 1,747 | 91 | 60 |
| 2,000-2,500 | 2,252 | 135 | 90 |
| 2,500-3,000 | 2,749 | 190 | 130 |

tendency for private investment to fall short of full employment saving, the whole process (average rate cuts at rate $b\%$ per annum with cyclical adjustment) would have to take place at a lower level of aggregate tax revenues. A further conclusion is that the process of tax reduction is likely, over the long pull, to be a periodic occurrence unless government outlay is to rise consistently at a rate considerably greater than the rate at which total output increases. We should also consider whether smaller, more frequent tax cuts might be more desirable than large reductions of the 1964-65 variety.

The Myth of Absolute Advantage

Perhaps the oldest, and certainly one of the most viable, myths in all of economics is that of "absolute advantage." Although absolute advantage is a logical impossibility in the context of interregional and international trade theory (as I hope to show in what follows), that has not prevented it from surviving to its one hundred and fiftieth birthday (or beyond if we credit Torrens rather than Ricardo with its origin).

I. Ricardo

The myth begins with Ricardo's exposition in his *Principles* [6, p. 71]. His familiar example is as follows:

To produce an equal quantity of cloth requires: in England, 100 man-years of labor; in Portugal, 90 man-years of labor. To produce an equal quantity of wine requires: in England, 120 man-years of labor; in Portugal 80 man-years of labor. And Portugal is said (in modern terms) to have an "absolute advantage" over England in production of both commodities.¹

Suppose we ask this question: Why does it take 100 man-years to produce in England an amount of cloth which requires only 90 man-years in Portugal? Ricardo says, "It would undoubtedly be advantageous to the capitalists of

¹ Ricardo's example is sometimes turned around with other writers by using an equal number of units of labor in both countries and deriving therefrom different amounts of product. Thus, Ricardo's example could be expressed by saying that with an equal quantity of labor: England will produce 90 yards of cloth or 80 gallons of wine; Portugal will produce 100 yards of cloth or 120 gallons of wine. This, obviously, does not alter the basic question raised, namely, why labor in Portugal is more productive than labor in England.

England and to the consumers in both countries, that under such circumstances the wine and the cloth should both be made in Portugal, and therefore that the capital and labour of England employed in making cloth should be removed to Portugal for that purpose" [6, p. 72]. This does not happen, according to Ricardo, because capital is not mobile between nations.

Consider the implications of the last paragraph: English labor and English capital are not in any inherent respect less efficient than Portuguese labor and capital. The only difficulty with English labor and capital is that *they are in England*. Move them to Portugal and the man-years required for them to produce the given quantity of cloth will drop from 100 to 90. What is it about Portugal that causes this increase in productivity? Ricardo does not say, and the explanation of why he does not say is because there is no reason. To provide a reason for the increase in productivity upon moving to Portugal would require the introduction of a third productive resource available in different proportions in each country or available only in Portugal in addition to labor and capital.² But, in logic, what could be proven about a combination of resources can be proven by limiting the number of resources to two. And to have two resources in one country and three in the other is to vitiate the analysis. Ricardo's original statement about the man-years required to produce the given quantity of cloth in the two countries is inconsistent with his other assumptions.³

II. *The Modern Treatment*

If Ricardo had not made the statement quoted above, his presentation would follow closely the usual modern treatment of absolute advantage in which there is no clear-cut statement that the productive resources considered are, or are not, identical in each location. In fact, what modern writers usually do is one of two things: (1) follow Ricardo and endow one location with a mysterious, and unidentified, *additional* resource which enhances productivity of the named resource(s) in that location, *or* (2) change the standard of measurement of a productive resource. In effect, they are saying that a "man-year" of labor in one location contains, say, 200 man-days in terms of produc-

²One possibility which might occur to the reader, especially since we are dealing with Ricardo, is that Ricardo did, indeed, have a third productive resource in mind—one found in both England and Portugal—land. We can discard this immediately for in Ricardo's thought rent was not a price-determining factor. Ricardo's international trade theory and his value theory are not, however, entirely consistent as is well known.

³Another possibility suggests itself. Could it be that English workers are dull-witted and their machinery rusty and slow in operation? We can note, first, that this was not Ricardo's assumption since merely moving the labor and capital to Portugal would not enlighten the one and oil the other. But can we "save the phenomena" by this assumption? The answer is "No." If we make this assumption, we can explain why England would have a lower per capita real income than Portugal but that is not what we are after. In fact, if we make the assumption we are saying that a "man-year" in England is not the same thing as a "man-year" in Portugal in terms of productivity.

One other thought—diminishing returns—we can discard immediately. Labor and Capital cannot both suffer, simultaneously, diminishing returns with respect to each other. Of course, the actual Ricardian assumption is of constant costs.

tivity, while in the other location a "man-year" contains 100 man-days.⁴ Of course, one can "prove" absolute advantage in this way, but the proof is not likely to be convincing. Since productivity is related to price for a resource and the resource price is related to the cost of production of the product, the two—productivity and cost of production—cannot be separated.

The term "absolute advantage" is also sometimes applied in modern treatments of trade theory to the production of *one* product in a location compared to the production of the same product in a different location (e.g., oranges in Florida and Maine). Analysis of such use will reveal that here, too, one of two different things is meant: (1) that the production can be produced in the favored location very much more cheaply than in the other location. This is merely a statement that the favored location has a large comparative advantage in production of that particular product relative to the second location. But comparative advantage does not become absolute advantage because it happens to be a large comparative advantage. This can be seen if we consider that we have no rule for saying when the comparative advantage in a particular case becomes so large as to cross the line into absolute advantage. Or, (2) that some physical reason makes it impossible to compare the two locations, for example, orange production in Florida as compared with Maine.

This latter case could be turned into a case like (1) above, if we observe that one *can* grow oranges in Maine (in a hothouse) but only at a cost very much greater than oranges may be grown in Florida. The more usual treatment, however, is to say that the same quantities of inputs produce different quantities of output in the two locations. Such statements contain the curious error of assuming that a production function knows where it is and acts differently in different locations. This would be so only if we put location explicitly into the function. But if we do that (e.g., one acre of Florida land in one function and one acre of Maine land in the other function), we no longer have the "same quantities" in both functions. Then, the fact that we get different outputs is not surprising and has no significance. The alternative—to leave location out of the functions, but allow location to affect output—is an obvious misuse of production functions in trade theory.

III. *The One-Resource Case*

"It is not so immediately obvious, but it is no less true, that international trade is mutually profitable even when one of the two countries can produce *every commodity* more cheaply (in terms of labor hours or all resources) than the other country" [7, p. 661]. I quote Professor Samuelson because the appendix to this trade chapter is an excellent, correct, elementary treatment of trade theory in real terms.⁵ No absolute advantage appears in the appendix.

⁴Sometimes a writer makes clear that this is so. See, for example [4, p. 49]. Here we are told explicitly that the land in two different locations is of different quality. Yet an acre of land in one location is treated as equivalent for cost calculations to an acre of land in the other location.

⁵I cite Professor Samuelson also because of the high professional regard in which he is held by economists—including this writer. If he has swallowed the myth, the rest of us do not have to be ashamed of having done so.

Nor can it appear in that (correct) treatment. What, then is wrong with the quotation, which is taken from the main body of the chapter? Let us see.

"... more cheaply (in terms of labor hours . . .)." The word "cheaply" implies money cost although it may be interpreted to mean "number of hours." However interpreted, we can accept it if we know that total cost per unit of product includes more than labor cost. But the original statement would not be a statement of absolute advantage unless we interpret labor to be the only productive resource. In that case we are back with the Ricardian error for that must mean there is some mysterious additional resource which makes labor more productive in one country than the other or we are changing our standard of measurement, and a "labor-hour" in one country does not mean the same thing in terms of productivity as a "labor-hour" in the other country.

IV. *The Two-Resource Case*

An easy way to see the error that economists make in the "more realistic" case of a two-resource model of absolute advantage is to look at a problem posed to students in a popular study guide accompanying a very successful principles text [1, pp. 16-17].

The problem is as follows:

| | <i>Economic Units [Areas]</i> | |
|------------------|-------------------------------|----|
| | A | B |
| Units of capital | 10 | 15 |
| Units of labor | 30 | 45 |
| Production: | | |
| Units of X | 60 | 60 |
| Units of Y | 20 | 25 |

One of the questions asked the student is which area has the absolute advantage. The answer given, of course, is that area A has the absolute advantage.

If a "unit of capital" is the same thing in area B as in area A, and a "unit of labor" is the same thing in area B as in area A, then if area B used 10 units of capital and 30 units of labor, it would produce the same output as area A, namely, 60 units of Product X and 20 units of Product Y. Now, as given in the problem, area B does produce 60 units of Product X, but produces 25 units of Product Y. It does this by using 5 *additional* units of capital and 15 *additional* units of labor.

Therefore, the last 5 units of Product Y *cost* 5 units of capital and 15 units of labor. This is impossible in the light of the costs implied in the rest of the table. In fact, consistency with the assumptions would require production in area B to be 90 units of Product X and 30 units of Product Y and there is no specialization (and no problem).

The only other way out is to say that a "unit of capital" in area B is not the same thing as a "unit of capital" in area A and similarly for a "unit of labor." In that case the numbers "15" and "10" for the amount of capital in each area, respectively, are noncomparable as are the numbers given for the

amounts of labor. But, then, the fact that production is different in the two areas would not surprise us, but we have no way to compare the two areas.

V. *The All-Resources Case*

"... more cheaply (in terms of . . . all resources) . . ." (See full quote beginning Section III, above.) If this is meant in real terms, our mysterious additional resource must be present in the favored country although how it can be when we already have all resources is not easy to see. If this is meant in terms of money costs, it is logically impossible. Since the demand for productive resources is a derived demand, there would be no demand for productive resources in the country with higher money costs for all products. What, then, would keep up the price of productive resources and, thus, money costs, in that country? The answer is "Nothing." Therefore, the prices of productive resources in the higher money-cost country would have to fall until the total cost per unit of producing some product was cheaper in that country than the other.

VI. *The Source of the Error*

The error, although it is not always easy to see, is made whenever absolute advantage is demonstrated in real terms. Let us look at Samuelson's example of absolute advantage [7, p. 663]:

| <i>Product</i> | <i>Labor Requirements for Production</i> | |
|--------------------|--|------------------|
| | <i>In America</i> | <i>In Europe</i> |
| 1 unit of food | 1 day's labor | 3 days' labor |
| 1 unit of clothing | 2 days' labor | 4 days' labor |

It is immediately obvious that a day's labor is not the same thing in Europe as in America in terms of productivity. We cannot, therefore, measure cost of production in terms of "labor-days" since these are not standard for both areas. Since products exchange according to their prices (assumed to equal cost of production where produced) we can conclude nothing about trade until we provide these prices. Since we have no *numeraire*, the only thing we can do is to express food costs in terms of clothing and clothing costs in terms of food. Thus we obtain relative prices for each product. When we do this we obtain the following table:

| <i>Product</i> | <i>Product Prices</i> | |
|--------------------|--------------------------------|--------------------------------|
| | <i>In America</i> | <i>In Europe</i> |
| 1 unit of food | $\frac{1}{2}$ unit of clothing | $\frac{3}{4}$ unit of clothing |
| 1 unit of clothing | 2 units of food | $1\frac{1}{3}$ units of food |

Expressed in this manner, no one is likely to be surprised to find that America specializes in food production, Europe in clothing production. But our table looks like the kind of table used to explain comparative advantage, not absolute advantage. The reason for this is simple: we cannot construct any table like Samuelson's without having it convert to a table like ours when we price the products being considered. (Except, of course, the uninteresting case in which prices are the same in both countries for each product.)

Now, the reason our table of prices will always turn out to be a comparative advantage table is also very simple. The only way the price of home-produced food can be higher in Europe than America is for the price of home-produced clothing to be lower in Europe than America. The only way you can be taller than your friend is for your friend to be shorter than you.

What Samuelson's table tells us is something quite different from what it purports to tell us. What it tells us is that per worker real income in Europe will be lower than per worker real income in America, that is, Europe is (very likely) a poorer country than America. What is called "absolute advantage" turns out to be something quite different—a demonstration that a poor country may trade with a rich country to the mutual benefit of both. This may be a useful thing to demonstrate, but economists should not treat it as one of two mutually exclusive cases (comparative advantage being the other). After all, no two countries in the world have precisely the same per capita or per worker real income so all trade is trade between a richer country and a poorer country. And all trade is based upon comparative advantage.⁶

VII. Conclusion

Is it not true that modern economists really know that absolute advantage does not exist—that it is a logical impossibility? After all, in solving the problem of trade in cases of absolute advantage we do convert the case to a comparative advantage case even though we tend to use awkward phrases like "absolute disadvantage" in the process. On this question I am inclined to take the naïve view that if we knew absolute advantage did not exist we would not write about it. As a matter of fact, there are examples which professional decency prohibits my citing in which an economist makes absolute advantage work only by having consumers, faced with the choice of paying two different prices for an identical product, choose to buy the higher-priced one. I do not believe economists should demand such a sacrifice of consumers in order to retain a cherished myth.

One way out for an author is simply to ignore the whole subject of absolute advantage rather than attempt to destroy the myth. At the text level of presentation this would appear much the best solution for pedagogical reasons. P. B. Kenen's little book [3, p. 7-8] follows this path as did my own effort [2, pp. 267-71] five years earlier. Both of these treatments obviously owe much to B. G. Ohlin's classic work [5].

In 1967, we celebrate the sesquicentennial of the publication of Ricardo's *Principles*. It would appear fitting that economists discard the myth of absolute advantage as a way of paying homage to that great figure in the history of economic thought.

ROYALL BRANDIS*

* The author is professor of economics at the University of Illinois.

⁶ We do not mean, of course, that differences in per capita or per worker real incomes are necessary as a basis for trade. Trade might well take place if these measures of economic well-being were equal in both locations or both countries. Those measures are simply irrelevant to any analysis of the basis for trade.

On the Determinants of Income Equality

The purpose of this note is to report further evidence of the tendency for the personal income of a region to be more equally divided the more maturely developed is the region. But more importantly our findings, which apply to the U. S. economy on a state cross-sectional basis, derive from an attempt to isolate development per se as a causal variable. Thus the conclusions reached in this study are not subject to the same criticism as might be directed toward "evidence" of the Kuznets [3, 4] phenomenon were it used to support the hypothesis of the state of economic development as a "reason" for income equality differences between regions or nations.

The results of our efforts to relate income equality in the states to development and various noneconomic factors, besides lending support to the above hypothesis, also point up the importance of racial barriers to increased income equality in the United States. The proportion of non-white population in the states is a significant explanatory variable (negatively) in the regression models of the study. Of additional interest, both the average age and the proportion of the population engaged in mining and manufacturing appear also as significant explanatory variables.

I. Introduction to the Models

The recent discussion in this *Review* concerning the Kuznets thesis that income is more equally divided in mature than developing economies involves a straightforward observational problem, its form ultimately depending upon the concept of income employed in constructing the data, the reliability of the samples, and the measures of equality used. It is obvious that these factors make a good deal of difference in determining the specific conclusions reached [8, 9, 15].

Of much greater significance is an understanding of the development process and reasons for such apparent distributional differences in income: Is there anything about the process of capital accumulation and hence economic development that tends to make the personal distribution of income become more equal? There exists only introductory work on the subject at present.

Soltow's article [14] indicates that educational level plays an important role in support of such a relationship, as shown by the existence of greater equality among more highly skilled or educated groups of people. And in an effort to explain the parallel movement of equality of the overall distribution of income and per capita income differences between the states, Smolensky [13] conjectures that increased mobility, particularly the movement from rural to urban areas during the period 1880-1950 in the United States, is the primary factor tending to reduce dispersion in incomes. While decreased regional dispersion is not necessarily coincidental with decreased dispersion within regions, one would expect that mobility tends to diminish both interregional and intraregional inequality in incomes if it is a significant factor at all.

Despite these efforts and the work of Kravis [2] and Kuznets [3, 5] elsewhere, there is no formal theory available which satisfactorily concerns itself with the relationship between development and the inequality of incomes. So the matter has generally rested on observations of the income distributions in a variety of countries, where the data bases used for such observations are rather different and thus lead to debatable conclusions concerning consistency or inconsistency with the Kuznets generalization. The question just raised cannot be broached with such observations and the recent discussion contributes but another set of them.

Recognizing that development inexorably brings many noneconomic changes, to approach the problem we pose it would be appropriate to hold social, cultural, and political factors constant in order to identify changes in the equality of income derived from the economic development process per se. And, certainly, comparability of the data used is a necessary ingredient in the observation process. The 1960 Census provides us with detailed data on the distribution of family income in the fifty states of the United States and, since data were similarly constructed in all cases and the political and economic structure is rather homogeneous at least across the continental United States, these data should yield some interesting insights into the impact of regional development on the personal distribution of income.

One would expect that social and cultural attributes have their impact on the distribution of income, Pareto's thesis not to the contrary [12]. Kravis suggests the following attributes which, aside from the state of development, could be expected to impinge on the income distribution: (1) human characteristics, (2) barriers to mobility, e.g., legal and such social barriers as are involved in racial discrimination, (3) economic structure, and (4) social and political organizations [2, p. 411].

Using the development hypothesis as a base, we have formulated a linear regression model for the states (excluding Alaska and Hawaii) in an attempt to explain variations in equality of the income distribution, as measured by the equality ratio,¹ by mean family income of the population as development indicator, and a variety of control variables which substantially implement the factors outlined by Kravis, as follows:

¹The area under the Lorenz curve as a percentage of maximum possible area. This measure is the complement of Gini's concentration ratio in percentage terms.

Quantitative Factors:

- Y : Area under Lorenz curve as a percentage of maximum possible area (measure of equality)
- X_1 : Percentage of population white
- X_2 : Percentage of population urban
- X_3 : Median school years completed
- X_4 : Percentage unemployment
- X_5 : Median age of population
- X_6 : Percentage of population employed in mining and manufacturing
- X_{13} : Mean family income

Qualitative Factors:

- X_7 : 1 if consistently Republican; 0 if not
- X_8 : 1 if consistently Democratic; 0 if not
(X_7 and X_8 both 0 if no voting consistency)
- X_9 : 1 if using sales tax; 0 if not
- X_{10} : 1 if using income tax; 0 if not
(X_9 and X_{10} may be both 0 or both 1)
- X_{11} : 1 if conservative state; 0 if not
- X_{12} : 1 if liberal state; 0 if not
(X_{11} and X_{12} both 0 if rated middle-of-the-road)

The dummy variables X_7 and X_8 are based on state voting records during the period 1940-60 in presidential elections, both variables assuming zero values if the given state was split 3-3 as between Republican-Democrat over the six elections considered. Obviously strict party affiliation is not a sufficient indicator of adherence to given social policies, particularly for some Southern states. Thus an additional set of dummy variables, X_{11} and X_{12} , is included to offset whatever biases may be inherent in X_7 and X_8 . These variables are assigned values on a purely judgmental basis and hence may be questioned on subjective grounds.²

Since we have little more than judgment to rely upon in anticipating the partial relationships of income equality and these variables, any speculating we do as regards these relationships cannot be derived from more than a naive theory except for the case of mean income, where the Kuznets thesis suggests a positive relationship.³ Without launching into a lengthy harangue concerning the remaining variables, for all of which some a priori case can be made, our interest centers more toward an evaluation of their relevance than testing any hypotheses about them.

² Here we use the terms "liberal" and "conservative" to denote, on a state basis, commitment to large redistribution and welfare programs or a basic *laissez faire* philosophy, respectively.

³ Thomas Hopkins, in a recent article [6] on the use of median income as an appropriate indicator of state fiscal capacity and/or need in the allocation of federal grants-in-aid, finds a strong relationship between state median income and the Gini ratio, using the 1960 data on families and unrelated individuals. One could thus justly expect a similar relationship between the Gini measure and mean income (for this study, mean family income) to present itself.

II. *The Empirical Results*

Table 1 contains the results of six alternative configurations of variables, with partial regression coefficients, *t*-ratios,⁴ and *R*²s (unadjusted) noted. It is significant to the reliability of these results that there is an overwhelming lack of intercorrelation in the independent variables, as seen in Appendix A.

Throughout the six variants, if a 99 per cent confidence level is used, the significant variables are (1) mean family income and (2) the percentage of population which is white. In variant (6) the percentage of the population employed in mining and manufacturing is also significant at the 99 per cent level. With respect to the behavior of net regression coefficients for X_1 and X_{13} it is interesting to note that they are very stable over five of six variants, with b_1 ranging between .17 and .21 in all but variant (4) and the estimated coefficient for mean income taking on values between .0018 and .0022 except in variant (5).

Thus it would seem that the Kuznets hypothesis is supported in a situation where a high degree of control is exercised over other population attributes, implicitly by the basic similarity of political and economic structure throughout the United States and explicitly by the other variables employed. The significance of X_1 as an explanator of variations in income equality would seem to enforce already prominent evidence on the effect of racial differences on income and its distribution.

Of the "traditional" variables other than X_6 , median age of the population is significant at the 95 per cent level in both variants (5) and (6). This variable could be expected to exhibit a negative partial regression coefficient for a variety of reasons⁵ but primarily because an older population would likely have a high degree of rigidity of skills and hence cause enforcement and proliferation of already established equality barriers. Variable X_3 , median school years completed, was chosen to describe the basic skill level of each state population and is significant in variant (6) at the 90 per cent level.

The significance of X_2 at the 80 per cent level is interesting also in light of Kuznets' views on income equality in developed versus underdeveloped economies. If we adopt the urban center as a focal point for capital formation, then through Kuznets' eyes we should expect a tendency toward greater inequality of income for those states with large urban population concentrations. While this conjecture is partially borne out by the data, the evidence is undoubtedly clouded by interactions with racial barriers in the urban center and the occupational mix variable, X_6 . Such interactions, while expected in general, would appear inconsequential for these data as inferred from the values for the appropriate correlation coefficients.

For the qualitative variables, in variants (3) and (4) a particular political affiliation and "philosophy" are of significance (95 per cent level) in explaining variations in income equality, X_7 appearing in variant (4) with a positive sign

⁴ Critical values for "*t*" are approximately ± 2.70 for 99 per cent, ± 2.02 for 95 per cent, ± 1.68 for 90 per cent, and ± 1.30 for 80 per cent.

⁵ See, e.g., Morgan [8].

TABLE 1—REGRESSION COEFFICIENTS
(*t*-ratios in parentheses)

| Regression Variant | Variables Included | | | | | | | | | | | | | R ² (d.f. in parentheses) |
|--------------------|--------------------|------------------|-----------------|-------------------|------------------|----------------|----------------|------------------|----------------|-------------------|-----------------|-----------------|------------------|---|
| | X ₁ | X ₂ | X ₃ | X ₄ | X ₅ | X ₆ | X ₇ | X ₈ | X ₉ | X ₁₀ | X ₁₁ | X ₁₂ | X ₁₃ | |
| 1 | .198 (6.39) | | | -.005 (-.020) | | .034 (1.24) | | | | | | | .00180 (5.68) | .78 (43) |
| 2 | .204 (6.04) | | | -.061 (-.025) | | .035 (1.25) | | | .623 (0.95) | -.355 (-.0.55) | | | .00176 (5.49) | .79 (41) |
| 3 | .210 (6.93) | | | .181 (0.76) | | .030 (1.11) | | | | | 1.690 (2.42) | .378 (0.49) | .00216 (6.36) | .81 (41) |
| 4 | .155 (4.82) | | | .131 (0.59) | | .027 (1.03) | 1.44 (2.12) | -.722 (-1.06) | | | | | .00183 (5.67) | .82 (41) |
| 5 | .211 (6.52) | -.057 (-1.92) | | -.096 (-.0.45) | -.293 (-2.18) | .069 (2.45) | | | | | | | .00265 (5.85) | .83 (41) |
| 6 | .172 (4.18) | -.041 (-1.33) | 1.020 (1.83) | .149 (0.64) | -.333 (-2.53) | .096 (3.16) | .440 (0.63) | -.074 (-1.02) | .430 (0.77) | -.344 (0.60) | .970 (1.27) | .761 (1.01) | .00204 (3.88) | .89 (34) |

(corresponding to a consistently Republican voting record), and X_{11} in variant (3) with a like sign (corresponding to a conservative political and social attitude). Both variables fall to significance levels below 80 per cent in the main equation, variant (6).

It is, however, inappropriate to use the individual t -ratios in Table 1 for assessing the importance of the sets of dummy variables, e.g., political affiliation as a structural variable, since the dummy variables in question were constructed in tandem. Thus to inquire after the statistical significance of political party affiliation requires that the joint hypothesis $\beta_7 = \beta_8 = 0$ be tested. A similar remark applies in the case of tax structure (X_9 and X_{10}) and political philosophy (X_{11} and X_{12}).

TABLE 2—STATISTICS FOR TESTING QUALITATIVE VARIABLES

| Basic Variant | Hypothesis | F -statistic | d.f. f_1, f_2 | Selected F -levels for rejection |
|---------------|---|----------------|--------------------|---------------------------------------|
| 2 | $\beta_9 = \beta_{10} = 0$ | 0.87 | 2, 41 | $F_{.99, 2, 41} = 5.17$ |
| 3 | $\beta_{11} = \beta_{12} = 0$ | 2.99 | 2, 41 | $F_{.95, 2, 41} = 3.23$ |
| 4 | $\beta_7 = \beta_8 = 0$ | 4.55 | 2, 41 | $F_{.90, 2, 41} = 2.44$ |
| 6 | $\beta_7 = \beta_8 = \beta_{11} = \beta_{12} = 0$ | 4.13 | 4, 34 | $F_{.99, 4, 34} = 3.93$ |
| | $\beta_9 = \beta_{10} = 0$ | 6.77 | 2, 34 | $F_{.995, 2, 34} = 6.22$ |
| | $\beta_7 = \beta_8 = 0$ | 8.03 | 2, 34 | |
| | $\beta_{11} = \beta_{12} = 0$ | 6.77 | 2, 34 | |

Table 2 presents the relevant F -statistics, using variants (2), (3), and (4) and variant (6) as bases for the testing of coefficients taking on zero values simultaneously. Seven hypotheses are considered, with primary interest centering on those within variant (6). For this case, each individual qualitative attribute of the states as well as the composite political factor (political party and/or philosophy) is significant at a 99 per cent level or above.

III. Some Final Remarks

The Kuznets observation is primarily interesting because it suggests that economic development per se may be a harbinger of social justice. The results of the present paper support such a hypothesis, and that is a rather comforting thought. This is not to suggest that social and economic policies designed to redistribute resources are useless, but, instead, that time and wealth accumulation are on the side of equality.

That the evidence indicates racial makeup as an important determinant of income inequality is not surprising. And, if the distribution of resources is an important aspect of overall social justice, then it would seem that recent pub-

lic policies designed to remove racial barriers in the social and economic market places of the United States are not misconceived, at least on the basis of their intent.

The Biological Interest Rate and the Social Utility Function

Samuelson [5] considered the problem of the optimal allocation of goods between per capita consumption of different generations living in a given period of time, in an economy with no capital and in which goods do not keep. He concluded that the optimal allocation would be the same as the allocation an individual would make for his own consumption in the different periods of his life, if he were facing a market rate of interest equal to the rate of growth of the labor force, which he called the biological rate of interest. Diamond [1] has extended this conclusion to an economy with capital, which is controlled by a central planning authority and is on the Golden Rule Path.

The Samuelson and Diamond economies are similar in two important respects: changes in investment cannot increase the amount of consumption goods available, and the allocation of these goods between the working and retired generations living in the same period is independent of investment decisions and the return to investment. These two attributes of the Samuelson model follow from its definition which ensures that any investment, or attempt to store goods, results in the complete loss of the goods involved, and therefore some universally observed rule is necessary to provide for the retired. In Diamond's Golden Rule economy, it can be shown that changes in investment cannot increase the flow of consumption goods, when alternative steady states are considered, even though the marginal product of capital is positive. The distribution of this maximum flow of consumption goods between the generations living in a given period is then determined by the central planning authority. In both models, therefore, the nature of the inter-generation allocation follows separately after the specification of the society's utility function for consumption of these two generations.

Samuelson approached this problem from the point of view of a representative man and used his representative man's utility function to decide optimal allocation, while Diamond's interpretation of the results obtained with the social utility function in his model, indicate that it too is identical to the utility function of a representative individual. However, a different formulation of the social utility function, and thus a different optimal allocation of consumption, is not only possible but may be preferable, even if the central planning authority is to be guided in its decisions by individual tastes. This alternative social utility function, which is concerned with the utility of all individuals living in a given period, was put forward by Lerner [2, 3] in his comments on Samuelson's article.¹ The points he raised also apply to Dia-

¹ The disagreement between Samuelson [6] and Lerner [2, 3] over the optimality of the biological rate of interest can be reduced to a disagreement over the appropriate social utility function. Should it be concerned with the utility of a representative man over the two periods of his life (Samuelson) or with the utility of all individuals living in a given period, with the relative weight given to the individual consumption of workers and retired determined by the representative man's attitude to consumption in the two periods of his life (Lerner)? Lerner believes that his approach should be followed because it does not depend, as does Samuelson's, on the indefinite extension of the rate of growth of the labor force. It deals with each period separately but always in the same consistent way.

mond's extension of Samuelson's conclusion to a Golden Rule economy. If population is growing, the number of workers in each period is greater than the number of retired. Use of the Lerner social utility function in such a situation, when there is no individual time preference, would result in equal per capita consumption of both groups, while the Samuelson social utility function would prescribe greater individual consumption for the retired.

Diamond's conclusion holds without qualification for a very special case which he does not consider in this context. In the individualistic and competitive economy he investigates in the main body of his paper, the consumption of the working and retired generations is determined solely, given the technical characteristics of the system, by their investment decisions and the return to investment. The only relevant utility function is that of a representative man. If this economy is on a Golden Rule Path, then the intergeneration allocation of consumption goods is the same as the individual allocation when facing the biological rate of interest.

I. *Social Compact or Centrally Planned Economy*

In Samuelson's economy, goods do not keep, and workers can only provide for their retirement by imposing restraints on their behavior which are also binding on all future generations. An individual life can be taken to consist of two equal periods, one of work and the other of retirement. The question he posed is, what common rule for the allocation of goods between generations will "lead each representative man to the highest point on his preference field?" [6, p. 520]. His answer, that this rule would provide an allocation identical to what an individual would make for his own consumption in the two periods of his life, if he were facing a market rate of interest equal to the biological rate of interest, is derived by using a social utility function which is identical to that of his representative man's. This can be readily demonstrated. Samuelson's society maximizes utility subject to the physical constraint of the output available. That is, it maximizes $U(c_1, c_2)$ subject to $c_1 + c_2/(1+n) = 1$, where:

output per worker is equal to unity;

c_1, c_2 represent consumption per capita of worker and retired generations, respectively; or, what is equivalent, it is the consumption of an individual in the two periods of his life;

n rate of growth of the labor force is assumed to be constant, with $L_1 = L_2(1+n)$;

L_1, L_2 the size of the worker and retired generations, respectively.

The optimal allocation then clearly must satisfy the condition

$$\frac{\partial U}{\partial c_1} \bigg/ \frac{\partial U}{\partial c_2} = 1 + n$$

and, given the specification of the utility function, this means that output is allocated between per capita consumption of the two generations in the same way that an individual would distribute his consumption if faced with a market rate of interest equal to the rate of growth of the labor force.

Another specification of the social utility function which gives a different result is, however, admissible. If the central planning authority is constrained to make its allocation decisions on the basis of individual tastes, that is, to treat individual consumption in each generation, in a given period, in exactly the same way a representative man treats his own consumption in the two periods of his life; then the social utility function must formally differ from the individual utility function. It must take into account not only per capita consumption and time preference but also the size of the two generations. A unit of output distributed to the generation with the fewer members will have a greater effect on per capita consumption than the same output distributed to the larger generation. If no adjustment is made for this, then the social utility function will be automatically biased against individuals in the generation with more members. To prevent this bias, its specification should be such that, for the same values, its marginal rate of substitution between per capita consumption of the two generations equals the ratio of their numbers multiplied by the individual's marginal rate of substitution between consumption in the two periods of his life. For example, if there is no time preference, then the planning authority's marginal rate of substitution,

$$\frac{\partial U}{\partial c_1} / \frac{\partial U}{\partial c_2}$$

should equal L_1/L_2 , when $c_1 = c_2$, since the individual's marginal rate of substitution in the same circumstance is equal to unity.² (If p is the rate of time preference, then

$$\frac{\partial U}{\partial c_1} / \frac{\partial U}{\partial c_2} = L_1/L_2, \quad \text{when} \quad c_1 = (1 + p)c_2$$

If a social utility function of the type described is introduced into Samuelson's analysis, the result obtained is superficially the same as his. Equilibrium is achieved where

$$\frac{\partial U}{\partial c_1} / \frac{\partial U}{\partial c_2} = 1 + n.$$

But now, in the absence of time preference, this means that $c_1 = c_2$ (or, more generally, $c_1 = (1 + p)c_2$), which is Lerner's solution. The optimal allocation of per capita consumption between the two generations is the one which individuals would make between the two periods of their lives if the rate of interest facing them were zero.

A Golden Rule economy, controlled by a central planning authority, has

² In his "Reply" [6] to Lerner, Samuelson gives a numerical example which makes use of an individual utility function (with no time preference) represented by $\log c_1 + \log c_2$. An equivalent social utility function which would give the same weight to the per capita consumption of the two generations as an individual does to consumption in the two periods of his life is represented by $L_1 \log c_1 + L_2 \log c_2$.

important similarities to Samuelson's pure consumption model. This economy is the dynamic analogue of a stationary state with a zero rate of interest. Although in an economy on the Golden Rule Path the marginal productivity of capital is positive and equal to the rate of growth of the labor force [4], the transfer of a unit of output from consumption to investment does not increase the amount of consumption available to society in any subsequent period [7]. Under the rules of the game, any change in the capital-labor ratio must be maintained permanently. The net output resulting from any subsequent increase in the capital-labor ratio, once the Golden Rule level is achieved, is at least completely absorbed in maintaining the new level. For individuals on a Golden Rule Path, further abstinence from consumption does not increase society's command over consumption goods³—they are in the same position as the individuals in Samuelson's model. This similarity is recognized by Diamond, but his analysis is incomplete, as our argument above shows, in assuming that the social utility optimal intergeneration allocation is necessarily equivalent to an individual's allocation when facing a market rate of interest equal to the rate of growth of the labor force. The correct comparison may, once again, be with individual allocation when the rate of interest is zero.⁴

The Samuelson-Lerner discussion brought forth cases in which one or the other consumption configuration is clearly to be preferred. If the labor force were to grow *forever* at a constant exponential rate, then the use of the Lerner social utility function would mean that *all* individuals would be worse off than if Samuelson's social utility function were used. But if the society were to be abruptly wound up at any time, then, as Samuelson admits [6, p. 522], the Lerner configuration might be preferable. There is a meaningful choice to be made between these two social utility functions.⁵

II. Individualistic and Competitive Economy

In Diamond's competitive economy the consumption of the retired is completely determined by their investment decisions and the returns to investment. They consume all their savings as well as the interest received

³ Let k be the Golden Rule capital-labor ratio and therefore $f'(k) = n$, with $f''(k) < 0$. If this ratio is to be permanently increased, to $k + \Delta k$, then the resulting increase in output per period is not greater than $f'(k)\Delta k$, or $n\Delta k$. The extra amount of capital required to maintain the new ratio is also $n\Delta k$, therefore the increase in saving does not increase consumption if the steady state is to be maintained.

⁴ It is clear from our analysis that in a centrally planned economy with a Lerner utility function, and with no individual time preference, the working and retired generations in each period will always have, unlike the Samuelson-Diamond plan, equal per capita consumption. But, if the planning authority gives equal weight to per capita consumption in each period, this level of consumption will increase from period to period as long as the marginal productivity of capital is greater than the rate of growth of the labor force. This supposition appears to be at variance with Lerner's statement that "the Samuelson plan *would* be optimal if one could really get \$2 for \$1 by postponing consumption and reaping the rewards of a positive marginal efficiency of investment" [3, p. 525]. However, if Lerner is assumed to be referring to the individualistic economy discussed below, there is no conflict.

⁵ For use as analytical tools in the development of optimal social security policies, which both Samuelson and Lerner briefly consider, the writer believes that the Lerner approach is preferable.

from the workers for use of these savings as capital during the production part of their retirement period. The society is completely individualistic; there is no inheritance. Because of this inter-relation between consumption and investment decisions, the allocation of consumption goods in one period between per capita consumption of the two generations, in a steady state, is the same as an individual's allocation of his consumption between the two periods of his life when faced with the constant rate of interest. His allocation satisfies the condition.

$$\frac{\partial U}{\partial c_1} \bigg/ \frac{\partial U}{\partial c_2} = 1 + r.$$

He consumes $c_1 = f(k) - rk - (1+n)k$, when he is a worker, and $c_2 = (1+r)(1+n)k$, when he is retired; where k is the capital-labor ratio, $f(k)$ is the output per worker, and r , the rate of interest, equals $f'(k)$. This is also the allocation of per capita consumption between the working and retired generations in a given period in the steady state. The amount available for consumption and investment is equal to the output of that period plus the initial capital, or $L_1 f(k)$ plus $L_1 k$. Subtracting from this quantity the total consumption of workers, $L_1 [f(k) - rk - (1+n)k]$, and their total investment $L_1 (1+n)k$ we find that the total consumption of the retired is $L_1 k(1+r)$, or $(1+n)(1+r)k$ per capita.

If this individualistic economy should not only be in a steady state, but also happens to be on the Golden Rule Path, then r equals n . There is here no separate problem of determining how to distribute the maximum amount of consumption goods between the two generations. The competitive mechanism ensures that the intergeneration allocation of consumption is identical to the individual's allocation of consumption between the two periods of his life when faced with the biological rate of interest. The Samuelson-Diamond configuration will prevail, without any qualification, only in this very special case.⁶

A. ASIMAKOPOULOS*

* The author is professor of economics at McGill University. This paper was written while I was a guest at Massachusetts Institute of Technology, on a leave of absence which was partly financed by a fellowship from the C. D. Howe Memorial Foundation. I am grateful to Professors P. A. Samuelson and W. C. Stubblebine for comments on an earlier draft.

⁶ There is no reason to expect that a competitive economy will necessarily reach a Golden Rule Path [1, p. 1135].

Time Deposits in the Definition of Money

The original study by Milton Friedman and David Meiselman [3]¹ on the competitive abilities of a stock of money and autonomous expenditures to predict money income in the United States has been subjected recently to an intensive reappraisal and review [1] [2] [4]. The essence of the arguments seems to be that the accuracy of autonomous expenditures in predicting money income or consumption depends critically on the definition of autonomous expenditures chosen as a predictor. To a lesser extent this same issue can be raised about the various possible inclusions made in constructing "the" quantity of money used for testing purposes. Essentially, the question boils down to the "moneyish" influence time deposits exert on the "narrow" stock of money (currency and demand deposits).

The analysis presented below purports to develop a pragmatic answer to this question by allowing annual first differences in three diverse stocks of money to compete at predicting annual changes in money income. In order to check the results of the simple correlations, annual first differences in the narrow stock of money and annual first differences in all time deposits are then structured in the form of a multiple correlation to estimate annual changes in money income. The multiple correlation analysis also tests the data for a significant coefficient of moneyiness in time deposits.

The raw data for currency, demand deposits, and time deposits may be used to construct an infinite number of money stocks. Each stock would include the first two of these items plus some percentage (weight) of all time deposits. F-M chose to include in their money stock the percentage of time deposits in commercial banks. Both expediency and logic recommended this choice. It is expedient because reliable estimates for this definitional stock of money can be obtained for a much longer time period than can be obtained for other money stocks;² and it is logical because of the distinct possibility that time deposits and demand deposits may be held as close substitutes for each other when they are claims against the same commercial bank. However, the case can also be made that the narrow stock of money is the only one that can be used for transactions and is, therefore, the only stock that influences spending.³ Yet another and contrary view sees *all* time deposits generating liquidity in the monetary system, and thus making more efficacious the spendability of the

¹ Hereafter, references to the work of these authors is abbreviated to "F-M".

² Reliable data for *all* deposits in commercial banks are available back to 1875, but accurate breakdowns of these data into time and demand components are available only from 1914.

³ This argument is tantamount to assigning irrelevant monetary influence to financial assets that are not transactive.

narrow money stock. Each of these concepts is logical, and each has intuitive plausibility. The choice, however, must be made in terms of the empirical relevance shown by the various stocks in predicting money spending.⁴

The groundwork for this study required time series data of the three most relevant stocks of money: the narrow stock, M_1 , the F-M stock, M_2 and the narrow stock plus all time deposits in commercial and savings banks, M_3 . Data for money income from the spending side, Y , were taken from the original work by F-M and supplemented to 1965 using their definition. Annual first differences in the various money stocks were then correlated with annual first differences in money income for the reference cycle periods defined in the original F-M study.⁵ The results of this series of tests are summarized in the first four columns of Table I.

The correlation values shown here make possible some interesting inferences that are obscured when only the values for longer periods are computed. First, the correlation coefficients for all the money stocks in most of the subperiods covered show extremely high degrees of association between changes in money and changes in income. Second, while the F-M money stock, M_2 , has the highest correlation value over the entire period, the narrow money stock, M_1 , has higher values in more of the years than either M_2 or M_3 . This seeming anomaly results from the inclusion of data from the war years (1942-46) in the tests, and the much poorer performance of M_1 in that period. Third, time deposits improve the correlation values only in the 1933-38 period.

The first inference—that any of the stocks of money influences spending—needs no interpretation beyond that given by F-M. Second, the irregular values for the periods embracing the war years obviously result from biases in the raw data and confirm Donald Hester's observation on the original F-M study, viz: "Indeed it is remarkable that the monetary model failed to reflect these conditions [in the 1942-46 period] more vividly" [6, p. 367].⁶ The raw data associations for the various money stocks and money income do not reflect wartime discrepancies because of the dominance of trend in the series. First difference correlations do emphasize the warpings of normal spending relationships by abstracting trend. Price controls, rationing, much higher taxes, and exhortations not to spend, dammed up money in peoples' pockets or caused "under the table" spending, the effects of which could not be measured. This alteration continued to some degree through most of the Korean War. The 1953-65 correlation values indicate a gradual return to more normal relationships.

Third, the better performance of M_3 during 1933-38 can be attributed to two "real" factors also not measurable cardinally. First, very low interest

⁴ This methodological postulate is the one adopted by F-M and not seriously challenged by anyone so far.

⁵ First difference correlations for the whole period are mentioned in the original study and are computed in a later investigation by one of the authors of this paper (Timberlake) [7], but only for the whole period (1897-1960) and the two half-periods (1897-1929) and (1930-1960).

⁶ F-M's effort to include *all* data in their original study is commendable, but surely they leaned too far when they included monetary and income data for 1942-46.

C., 1960, Series X, p. 646. Data for M_2 and Y to 1957 were taken from [3, pp. 259-60, Table II-B]. Data for the period 1953-1965 were obtained from current issues of the *Survey of Current Business* and the *Federal Reserve Bulletin*. Percentages in Column (5) were computed by the authors.

^a Most of these values correspond to ones given by $F-M$ in [5, p. 375, Table I].

^b Separate estimates for demand and time deposits in commercial banks before 1913 are not reliable.

^c These values are for the correlation coefficient of *time* deposits on income. The computer kicks out only the higher of the two values in a multiple correlation (without regard to sign). To compare the simple coefficient of the narrow stock of money on income, see Column (2).

rates on time deposits discouraged their attractiveness as investments and encouraged their use as quasi-transaction balances. Probably more important, however, was the influence of the bank debacle in the early 1930s on deposit holdings. Demand deposits lost some of their moneyness due to the additional risk imputed to them by depositors after the monetary blood-letting of 1932-33. Time deposits seemed less risky to both banks and their depositors, so the deduction reasonably can be made that moneyness was lost by demand deposits and gained by time deposits.

To test these conclusions further, and also to test for a significant monetary coefficient of time deposits, a multiple regression analysis was conceived using first differences in the narrow stock of money, M_1 , and in all time deposits, T , to predict changes in money income, Y .⁷ The form of the testing equation is:

$$(1) \quad \Delta Y = a + b_1 \Delta M_1 + b_2 \Delta T,$$

or

$$(2) \quad \Delta Y = a + b_1 [\Delta M_1 + b_2/b_1 \Delta T].$$

If time deposits have some degree of moneyness, the ratio (b_2/b_1) should be greater than zero but less than one. A value of one for this fraction would imply that time deposits had moneyness equal in degree to the items in the narrow stock of money. A negative value for (b_2/b_1) implies that time deposits serve more in the nature of investments: that people actively reduce their transactions balances to "buy" time deposits.

As can be seen from Table I, the fraction (b_2/b_1) is between -1 and 0 except for the period 1933-38. In this period the ratio jumps up to 7.997 ! Furthermore, bringing time deposits into the picture as a multiple correlate to the narrow stock of money does not add significantly to the simple correlation coefficient in any of the periods except 1933-38. [See Columns (9) and (10).] But in this period first differences in time deposits are better predictors of changes in money income than are changes in the narrow money stock, and the multiple correlation coefficient becomes a whopping $.987$! Such dramatic results confirm the supposition that time deposits gained appreciably in moneyness due to the depreciation in confidence people had in demand deposits.

The value for (b_2/b_1) then becomes large and negative for the periods that include the war years, emphasizing the efforts of people to keep purchasing power they were enjoined from spending in a form that obtained some return. Only in the last 12 years does the ratio of (b_2/b_1) become a positive fraction of a magnitude that would give some credence to the theory of moneyness in time deposits, and even in this case the additional predictability gained from including time deposits in the analysis is insignificant ($.667$ to $.692$).

Surplus Agricultural Labor and Development— Facts and Theories: Comment

In a recent communication [1] Morton Paglin presented data on Indian agriculture in an attempt

... to show that large-scale opportunities for additional employment exist within agriculture, and that the output of the current labor force could be increased by redistribution of labor within the sector. Chronic or disguised unemployment of family labor, presumably because of small landholdings, will also be called into question as a generalization applicable to farms in the smaller size classes. Finally, the common assumption that economic development will produce a large exodus of labor from agriculture is shown to be in need of drastic revision [1, p. 816].

From his interpretation of these data he concluded that they

... throw doubt on the validity of the dual economy models which assume a free transfer of labor from agriculture to industry without loss of agricultural product. The evidence also negates those formulas which suggest a maximization of output via the maximization of the average productivity of capital. ...

Finally, on the basic issue of the zero marginal product of labor and disguised unemployment, the evidence offered here supports the position taken by Viner, Schultz, and Oshima, against the more generally accepted views of ... many others that Indian agriculture suffers from a redundant labor force with a zero marginal value product. The data indicate not only a positive marginal product of labor, but also lend support to the hypothesis that the rationalization and improvement of agri-

cultural techniques, generated by development efforts, will exert a strong upward pull on the demand for agricultural labor [1, pp. 831-32].

The following comments show that the data used by Paglin in his article, insofar as they are relevant to the above subjects, clearly support the opposite conclusions.

I. Paglin's Data and the Return to Capital

In Columns 2-6 of Table 1 are presented the relevant data on inputs and outputs of Indian agriculture from Paglin's Tables 1, 3, and 4. Labor input in rupees is "all cash outlays for hired labor" and "family labor of men, women, and children is given an imputed value equivalent to the market wage appropriate to each category." Other Type A costs are all nonlabor "cash outlays for . . . seed, etc., except for rent paid by tenant farmers" plus "depreciation of equipment" or, alternatively, "working capital, depreciation of fixed capital, . . . , etc." Rent in Table 1 is the difference between Paglin's Type A and Type C inputs, which is "rent, paid and imputed." Gross output is the "value of agricultural output (in rupees)." Profit—the difference between gross output and total costs—is identified by Paglin as "entrepreneurial profit."

These are the only definitions of the concepts which were given by Paglin. In order to evaluate carefully the data presented, one would need a substantial amount of additional information on (1) the basis for computing imputed labor costs, (2) the specific items which were included in Other Type A costs, (3) the basis for computing depreciation, (4) the percentage of Other Type A costs accounted for by depreciation, and (5) the extent to which rent is a payment for the services of capital and the extent to which it is payment for the use of land. In this comment we assume that sufficient information on (1) and (2) would lead us to use Paglin's data. The information for (3) and (4) is needed to obtain an estimate of the quantity of capital per acre for the various size groups; we will have to proceed without this information.

However, it is impossible to avoid a discussion of Paglin's data on rent. Paglin asserts that systematic differences in fertility among size groups were unlikely [1, pp. 816-18]. If his rent figures reflected differences in fertility and location, then he is correct in noting that this would support the surplus labor hypothesis. On the other hand, if differences among size groups do not reflect differences in land quality, then they reflect either differences in bargaining power or differences in "rent" on improvements. Paglin does not suggest the former, and since some rents are imputed this explanation would be difficult to accept. Thus, deductively we arrive at the conclusion that differences in rent largely reflect differences in returns to capital improvements. This interpretation of the statistics is also borne out by the high correlation of Type C inputs per acre with gross output per acre—especially in view of the curiously unresponsive reported rent data for Madhya Pradesh. Paglin reports a correlation coefficient of .94 for the log of Type A inputs with gross output, and .91 for the log of Type C inputs with gross output. One suspects that if the effects

Source: [1, pp. 817, 822-23].

of the Madhya Pradesh rent data had been eliminated from the latter regression, it would have explained more than the former.

One feels relatively safe, then, in assuming either that fertility and location improved as the size of farm declined in a region or that returns to differences in capital improvements largely accounted for differences in rent among different size groups in a region. The importance of these assumptions becomes apparent in Section III below.

II. *Optimum Factor Combinations*

Paglin never explicitly shows profits per acre (Column 7, Table 1), but several times he implies that his data show a direct relationship between labor inputs per acre and profits per acre. For instance he says "... the present data ... show clearly that hired labor adds considerably to output, and the employer hires this labor not because of social pressure but because it is profitable." He also refers the reader to "low-aspiration" models to explain "poor utilization" of larger holdings [1, pp. 824, 828].

He does not note that profits per acre were highest for the size group using the *least* labor per acre in West Bengal and Uttar Pradesh, and that in Punjab the largest size group had highest per acre profits and a labor per acre utilization virtually the same as the lowest. In Madhya Pradesh and Madras the size groups with lowest labor inputs per acre were the second most profitable per acre; in Madhya Pradesh the size group with highest labor inputs per acre was the most profitable per acre, and in Madras the size group with the second highest labor inputs per acre showed the highest profits per acre. Thus, it is seen from Table 1 that, of the twenty-nine factor combinations alternative to the *least* (or virtually the least) labor per acre combinations of their region, only two would increase profit per acre. Let us analyze these two exceptional cases more closely.

The systematic and large variations in rent per acre in all other states make one reluctant to accept the reported rent figures of a constant 30.0 rupees per acre for Madhya Pradesh. If, in fact, rent was a modest 23 per cent higher for the smallest size group than for the least labor-using size group, then the latter would be the most profitable per acre in Madhya Pradesh.

Thus, only in Madras is it clearly true that the *least* labor-using size group was not the *most* profitable *per acre*. But profit per acre alone has little relevance for the decision on choice of factor combinations. Of much greater relevance is profit per unit of capital invested, and Paglin shows no figures on capital invested nor does he discuss the opportunity cost of using capital in agriculture. In fact Paglin seems to suggest that credit availability theoretically would be the only factor limiting the application of additional capital per acre in India. He does at that point mention the supply of capital goods (irrigation field channels), but he dismisses this limit on the grounds that its production is labor intensive. However, the opportunity cost of investment, even if it only involves payments to labor, certainly should be considered by the private Indian farmer.

By making two assumptions we can estimate crudely the additional capital required in Madras to change from the least labor-using technique to the most-profit-per-acre technique. Assume that the labor-intensive technique is double cropping and that the alternative is not, so that one-half of additional Other Type A inputs (seed, equipment, depreciation, etc.,) represents a conservative estimate of additional working capital requirements. Further assume conservatively that differences in rent input represent a 25 per cent return on improvements. (If we assume a smaller percentage return, the capitalized earning value of the improvements would be even larger.) On the basis of these assumptions a shift to the labor-intensive technique in Madras would require an investment of 29.4 rupees $[\frac{1}{2}(86.8-27.9)]$ of working capital and 134.0 rupees $[(55.2-21.7)/.25]$ of improvements—a total additional investment of 163.4 rupees per acre to increase profit and rent by 42.5 rupees per acre. This gives a 26 per cent return on the additional investment. The return falls below the assumed opportunity cost (25 per cent) of capital if working capital requirements are underestimated by more than 6.6 rupees per acre or if equipment costs (which are assumed to be the same) are more than 6.6 rupees greater for the labor-intensive technique. If the opportunity cost of capital is assumed to be only 10 per cent, then the above calculations yield an increased necessary investment of 364.4 rupees per acre and an 11.7 per cent return on that investment—which would drop below 10 per cent if working capital requirements were underestimated by more than 60.6 rupees or if additional equipment requirements were more than 60.6 rupees. These calculations show that consideration of even a modest degree of uncertainty would lead us to reject the hypothesis that owners of large farms even in Madras were not profit maximizers.

Paglin's data, then, lead us to conclude that it is misleading for him to say of Indians that

Since the farmer with a relatively large holding can eke out a moderate income without the trouble of hiring a high per cent of nonfamily labor, or the risk of borrowing additional working capital for other inputs associated with intensive cultivation, he frequently seems to prefer the low-effort, low-risk, low-output package to the higher-risk, higher-profit, higher-output combination [1, pp. 827-28].

and to say *on the basis of his data* that

... limited incentives in many areas of Indian agriculture, rather than a critical man-land ratio, may be the more important bottleneck to increased production and employment. However, insofar as population growth leads to smaller average holdings through a breakup of the larger holdings, and to the extent that current government land policies produce a more equitable distribution of land, the bottleneck is relaxed and a safety valve, effective at least in the short run, is brought into play [1, p. 828].

Undoubtedly there are cases of underutilization of labor on land in India, and we agree with Paglin that output could be increased if this were not the case, but his data indicate that these cases are exceptional rather than general.

III. *The Marginal Value Product of Labor*

None of Paglin's data bear directly on the question of the marginal value product of labor in Indian agriculture. With some assumptions we can use his data to cast some indirect light on this question. In Table 2 (Column 5) we present data on the change in gross output per acre less nonlabor inputs per acre which would accompany a shift in each region from the least labor-using technique (except for Punjab where we use the second least labor-using technique) to each of the alternative techniques. Ideally to measure the marginal value product of labor we would wish to vary the labor costs as all other costs were constant. It is usual to permit some obviously complementary inputs such as seed costs to vary with labor, but to measure revenues net of these costs; Paglin does not follow this procedure. We assume that rent differentials within each district measure differences in "rent" on improvements and/or differences in returns resulting from differences in fertility and location between size groups. By deducting differences in rent from gross output per acre (from Table 1) we are eliminating to some extent variations in revenues resulting from differences in improvements, fertility, and location; but we are unable to eliminate variations in output due to differences in working capital and equipment requirements. For comparison, changes in labor costs are also shown (in Column 4) for these alternative techniques.

From these data it is seen that the "marginal value product" of labor was significantly negative for all alternatives to the *least* labor-using technique in Punjab and Uttar Pradesh. The rent data for Madhya Pradesh discussed earlier make us suspect that the same was true for that state as well. For West Bengal four of the seven alternative techniques had "marginal value products" of labor which were positive, but in no case was that "marginal value product" as much as one-half of the "marginal cost" of labor. Thus, only in Madras do we find "marginal value products" of labor high enough to cast doubt on the assumption of zero marginal value product of labor—and in Madras only for two of the seven alternative techniques. And if it is true, as seems likely, that working capital and equipment requirements increased significantly as labor, seed, and other current costs increased significantly, then these data understate significantly the extent to which the "marginal value product" of labor was negative generally in India.

IV. *Rationalization and the Future Course of Indian Agriculture*

Paglin was successful in his attempt to show "that the output of the current labor force could be increased by redistribution of labor within the sector [“1, p. 816]. His data do not show that an increase in the quantity of agricultural labor would result in an increase in aggregate agricultural net product, unless we assume that capital is a free good. Let us use "rationalization" to mean redistribution of laborers among the acres of land in these five regions in such a manner that the aggregate net product is at least as great as at present, *aggregate capital stock is no greater than at present*, and aggregate labor input to obtain that output is minimized. The output which is socially significant is Paglin's gross output less Other Type A costs, since only this net output can add

to the welfare of an Indian. The data for this net output per acre are presented in Column 6 of Table 2.

For Punjab and Uttar Pradesh we see immediately that by using all the acres as the largest size groups were used, we could use a substantially smaller quantity of labor and obtain a substantially larger quantity of net output. With data on the aggregate number of acres in each size group we could calculate the quantity of labor cost released by operating the entire region as the largest size groups were operated; with data on labor cost per man-hour of labor we could estimate the number of man-hours so released. On the formerly small-size farms extra working capital, equipment, and improvements per acre and per worker exist after the rationalization, but we are not permitted to use them in Punjab and Uttar Pradesh *and depreciate them*, since their depreciation was one of the Other Type A costs which made the marginal net product of labor-capital negative. Temporarily we can substitute the improvements for some of our remaining labor until they must be replaced, but we will permit the released workers to take their proportion of the equipment and working capital with them as they move to other regions.

Next we must decide to which region these surplus workers should be moved. They will have the equipment and working capital which they used in their native regions, but they cannot take with them the improvements with which they labored. The rent data in Table 1 for Madhya Pradesh, Madras, Punjab, and Uttar Pradesh indicate that improvements per acre were greater for all other production techniques than they were for the least labor-using technique; hence, from these data we get no clue concerning what happens to the marginal product of labor-capital as the improvements-labor ratio declines. From the data for West Bengal we do get such a clue when we analyze data for the three largest size groups. For the "7.51-10 acres" and the "15 acres and over" groups, labor costs were approximately 10 rupees per acre greater than for the "10.01-15 acres" group; Other Type A costs increased with size, and rent decreased significantly as size increased. Net output per acre decreased significantly as size increased; hence, as the improvements-labor (or fertility-labor) ratio declined, even with the equipment-labor ratio rising, net output per acre and per worker declined. Thus, we conclude that the "marginal value product" of this labor released from Punjab and Uttar Pradesh will in all probability be lower than that indicated for the other regions by Paglin's data. And as we noted in Section III, only in Madras was that "marginal value product" clearly positive.

The significant point of the analysis is that, while labor can be removed from Punjab and Uttar Pradesh without loss of output, *all of this labor* cannot be added in the other regions without reducing the capital-labor ratio and, thus, reducing the marginal product of labor. This is because improvements cannot be transferred with the labor and, without violating the requirement of a constant quantity of aggregate capital in agriculture, only the depreciation on the improvements with which the transferred laborers formerly worked can be used to accumulate improvements in their new location. Thus Paglin's data indicate that by moving workers out of agriculture net agricultural output

TABLE 2—SELECTED DATA ON LABOR PRODUCTIVITY

would increase, but they do not indicate that increasing the number of workers in agriculture can increase net output, unless capital is assumed to be costless.

We agree with Paglin that there probably is no significant limit to the absolute quantity of output per acre of Indian land if additional labor *and capital* are applied. However, we find it impossible to follow him in assuming that in India capital should be regarded as a free good. Capital is scarce in India, as it is in the United States; for this reason the opportunity cost of using it in agriculture must be considered in private and public planning. From Paglin's data it appears that generally in India the farmers in the larger size groups have considered this opportunity cost of capital to a greater extent than farmers in the smaller size groups. One hopes that India's public planners will continue to concentrate on changing techniques in agriculture, to consider the opportunity cost of investing in agriculture, and to analyze carefully their accumulating body of facts.

ROBERT L. BENNETT*

Reply

Dr. Bennett raises some important issues but his attempted resolution of the problem reveals the inadequacy of a mechanical application of the theory of the firm to peasant agriculture. Apparently having little knowledge of Indian agriculture, Bennett fails to see which assumptions underlying the market economy model of the firm have to be modified for the average Indian farmer who purchases only a small percentage of his inputs, whose capital stock and land improvements represent in large part accumulated family labor in the classical sense, and whose objective is not just to maximize entrepreneurial profit but to maximize farm business income (the total return to all factors owned by the farm family) and yet keep the family functioning as a unit. This latter constraint means that the imputed wage rates for women and children¹ applied to part of the family labor inputs, as well as imputed rent and interest used in the input figures, are not always viable economic alternatives for the Indian farmer. From the social point of view it is also questionable whether the entire family labor force used on the farm could be used outside agriculture. Legally child labor is prohibited in industry and the part-time agricultural labor performed by women with families may have little use in the industrial sector. Thus the opportunity cost of a considerable portion of the labor inputs used on the family farm may be near zero.

¹ In the Farm Management data they were valued at $\frac{3}{4}$ and $\frac{1}{2}$ of the male wage-rate.

If the farmer were to rent his land at the imputed figure, the family labor income would be both precarious and probably smaller. Operation of the farm provides guaranteed employment for the family labor force and the opportunity to transform some of this labor in off-peak periods into capital through the digging of irrigation channels, the building of farm structures and fences, the raising of work animals, etc. There is probably an underestimation of the output in the subsistence sector by not taking into account the value of the capital formation. This phenomenon of direct transformation of labor into capital explains how seemingly overpopulated agricultural areas have been able to absorb and support additional workers by the tens of millions. When Bennett speaks of scarce capital yielding a better return outside agriculture, he doesn't realize that the family labor transformed into agricultural capital cannot alternatively be transformed into industrial capital without scarce foreign exchange and other capital being used in the process.

Bennett's first technical error lies in his assumption that the imputed rent figures measure intrinsic soil fertility or permanent improvements on the land which are independent of the level of inputs used: "We assume that rent differentials within each district measure . . . differences in returns resulting from differences in fertility and location between size groups. By deducting differences in rent from gross output per acre we are eliminating to some extent variations in revenue resulting from differences in improvements, fertility, and location." Let us review the evidence on rent insofar as it bears on this problem.

If we assume that the farms randomly selected in each sample district show no correlation between intrinsic fertility and size, then differences in the marginal productivity of land would still appear if the larger farms using hired labor were applying inputs much less intensively than the small farms using mainly family labor, part of which had a lower opportunity cost. The marginal product of land would increase as inputs of labor per acre went up and the marginal product of labor declined. I previously gave evidence that Indian farms in fact correspond to the above hypothesis. The field work of such careful observers as J. W. Mellor and T. V. Moorti, who analyzed sample farms in Agra, Uttar Pradesh confirms the judgment that the land of the larger, wealthier farmers is not intrinsically inferior to the land of the smaller farmers but that frequently the labor inputs are "too thinly applied" on the large holdings—cited in [6, pp. 825, 827n]. Differences in rent would be the *result* of varying inputs per acre and not an independent causal factor in explaining output variations as Bennett assumes. It is for this reason that the inclusion of imputed rents in the input data "C" *reduced* the percentage of explained variance in output as compared to results obtained when rent was eliminated from the inputs ("A" data) [6, p. 819]. If this hypothesis on rent is true even in part, then we cannot assume that small farms reorganized and cultivated with the lower inputs now prevailing on the large farms would earn the same rent differentials as before. Yet this is exactly what Bennett postulates in his Table 2 ("adjusted net revenue") and the discussion connected with it.

The survey workers in attempting to estimate the rental value of each farm

(typically made up of several scattered fragments) had little in the way of market guidelines. India, especially since the Zemindari laws, is a nation of peasant proprietors, and 80 to 90 per cent of the land is owned by the cultivators. Of those who do rent land, only a tiny fraction pay rent on a fixed cash basis. Rather, the wide variety of arrangements commonly used make the landlord a participating entrepreneur who sometimes contributes seed, etc. and who gets a certain percentage of a highly variable pie. Even the rented land provides no adequate sub-sample for imputing specific rent figures by size of farm. Faced with the requirement of imputing rent to each farm, the survey workers in many cases used the land tax as an indicator of rental value. Unfortunately, land assessments in India are frequently 30 and 40 years old, and there is the well-established tendency to underassess larger properties. There is also every reason to believe that the Indian tax assessor was not capable of soil analysis but, if anything, based his notion of land value on output per acre which would reflect the higher marginal productivity of land due to higher labor inputs on small farms.

I do not think there is any strong reason for believing that in each fairly homogeneous sample area the larger farms would be systematically inferior in soil quality to the smaller ones, especially since small and large holdings are thoroughly fragmented and interspersed.² In any case, natural fertility is now rightly considered of less importance than it once was. E. Boserup in her extensive report of agricultural practices in underdeveloped areas has suggested that fertility in the classical sense as a fixed quality of land should be replaced by the concepts of frequency of cropping, long-fallow, etc. [1, p. 13]:

Traditional economic theory . . . regarded as immutable natural conditions many features [of land] which scientists now consider to be man-made and, in particular, the distinction between naturally fertile land and less fertile land was considered a crucial element in the explanation of agricultural change. . . . By contrast, when the analysis is based upon the concept of frequency of cropping, there can be no temptation to regard soil fertility exclusively as a gift of nature, bestowed upon certain lands once and for all. Thus, soil fertility, instead of being treated as an exogenous or even unchangeable initial condition of analysis, takes its place as a variable, closely associated with changes in population density and related changes in agricultural methods.

She then develops the thesis that increases in agricultural density induce a shift from a low input, long-fallow technique, to more intensive methods involving short-fallow, multiple cropping, and more labor-intensive crops of higher value. Also particularly relevant to our discussion here are the historical and current examples (including India) in which reductions of agricultural population density have led to a deterioration of agricultural practices, a ne-

² But A. K. Sen has suggested (*Economic Weekly*, Feb. 1964) that small farms may be more fertile than large ones because the superior survival rate of children on fertile farms leads to more rapid subdivision. Our analysis below suggests that given a random distribution of fertility (re farm size), the families with small farms and higher labor-land ratios are induced to shift to more intensive cultivation, making the land appear more "fertile." The data on irrigation-use and double cropping support this position [6, pp. 818, 825n].

glect of the soil and a consequent deterioration of "fertility" [1, pp. 62-64]. I do not think it is necessary to spell out all the consequences this analysis has for Bennett's calculations of "adjusted net revenue" and marginal productivity—both of which are based on the concept of intrinsic fertility differences. The dire results stemming from "declining labor-fertility ratios" would also seem to evaporate.

If then differences in fertility in any one region are less important than intensity of cultivation as an explanation of output, (and for the other reasons cited), it makes sense to look at the total surplus (rent and profit) generated by different levels of input. Now for this total we do have reliable figures (gross output minus type "A" inputs). These are given in Table 1. Most of the farms previously appearing as economically untenable now are seen to earn a surplus. If we set up maximum profit and rent per acre as a test of efficiency, then the appropriate procedure is to see how many groups are below, and how many above, the input level of the optimum group. (This would also be the correct method to use with Bennett's profit figures.) In place of Bennett's conclusion that only two out of 29 factor combinations could improve their position by increasing inputs, we find that 16 out of 29 could do so—these are mainly the medium and the larger farms in West Bengal, Madras, and Madhya Pradesh. Since all labor and capital inputs have been priced at the market rate, including imputed wages and imputed interest where necessary, it is reasonable to suggest that these farms are operating below the optimum level—that is, underutilizing their land. On the other hand, 13 groups which are below the profit-rent maximum have higher levels of inputs per acre, implying that the marginal productivity of labor has fallen below the imputed value of labor used in the input data. The last two columns of Table 1 show deviations of labor inputs and deviations of net product from the best performing group. They represent revisions of Bennett's adjusted net revenue data in line with the previous argument that varying inputs, not intrinsic fertility differences account for variations in net product. Given the size distribution of Indian farms, the underutilized large farms include a much larger total acreage than the smaller ones which have exceeded the optimum point [5, p. 48]. This means that a given reduction in labor inputs per acre on the small farms can be absorbed by a lesser increase in labor inputs on the large farms.

I do not share Bennett's belief that the marginal product of capital and labor shifted to these states would be negligible when the data show that increasing rents and profits per acre are obtainable with higher inputs. His speculation about the offsetting effects of a declining "fertility-labor ratio" is based on the static and erroneous notion that the imputed rent figures accurately measure fertility and that fertility is a fixed inherent quality of the soil that is unrelated to cultivation techniques. He also neglects dynamic factors. The Indian experience with movement of populations into new areas showed these populations to be more receptive to improved agricultural practices (which shifted the production function upward) than the long-established population in the area—a break with their old environment apparently

^c Differences in net product between group with maximum rent-profit and all others.

induced them to give up traditional agricultural techniques [2, p. 114]. As for improvements (such as irrigation field channels), they tend to be a function of more intensive cultivation, i.e., more labor per acre in crop production, and

are a kind of bonus resulting from the greater number of labor hours which then become available in the off-peak months when the alternative use of such labor is limited or nil.

But there is a much more fundamental point relevant to the question of moving family labor out of agriculture. For a market economy where most of the inputs are purchased (both current and capital goods) and the output is sold, the true net output of the farm can be clearly determined. India's farms, particularly the small ones, have a remarkably low level of monetization of inputs—in Orissa only 8 per cent of the inputs are cash, in Uttar Pradesh 23 per cent [3, p. 61] [4, p. 81]. These are averages; the small farms drop below the stated figures. While Bennett's net revenue would be a close measure of net product in a market economy, it significantly understates the true output of family farms in India. The error lies in neglecting to include in total output the value of capital goods (bullocks, fences, buildings, sheds, etc.) that are largely produced with family labor (given an imputed value of market labor) but depreciated and charged as a cost against crop production. These depreciation charges are included in type "A" costs and reduce the net value of the farm crops, but in fact are not paid out, and family income is not thereby reduced. Hence output is understated if there is no estimate of the value of capital goods produced on the farm. Labor expended on the production of capital goods must also be added on the input side, but since this is family labor—much of it with zero opportunity cost—there is a question as to whether imputed labor inputs should be increased.

This underestimation of net output is more pronounced on the smaller farms because cost data show that capital maintenance and depreciation charges per acre are higher as the size of farm declines, while the percentage of purchased capital assets is lower. This is most apparent in bullock charges (a major cost item, second only to labor) and depreciation of farm structures. Bullocks are bred and raised on the farm and are an important element of capital formation. A detailed breakdown of the cost of raising bullocks shows a minor cash expenditure for concentrates and medicine, the rest being non-cash expenditures of imputed family labor used in tending the animals and gathering fodder for them, depreciation of animal sheds, etc. The annual costs of bullocks are then converted into daily costs and charged against the various crops as inputs. Regional grain prices determine the gross value of crops.

Since we have no estimates of the total value of capital goods produced on the family farms, we could use the Farm Management depreciation figures as a measure of such output, but this understates the output in cases where net capital accumulation is taking place—that is, where gross capital formation exceeds depreciation. The basic problem here involves imputing value to inputs which have little opportunity cost and where the capital goods produced have no market price. If we place a zero price tag on the family labor units used in off-peak periods to produce such goods, then the net value of crop production will correspond to the actual net product which the farmer retains—his farm business income. As we raise the imputed price of family labor, the net value of crop output drops and the imputed value of capital

goods (on a cost basis) rises, but capital goods are not usually included in estimates of farm output.

To a large extent, the appropriate price to attach to family labor depends on the problem being considered. In the surplus labor problem, the question is one of matching gains from added labor inputs in industry against possible losses of agricultural product. In this case only the family labor that can be used in industry should be given an imputed wage in agriculture. It would justify placing a zero price tag on a significant portion of child and female labor. How would this affect the relative net output figures of small and large farms? Women and children work both in the fields and on maintenance, tending bullocks, etc. Let us assume that all labor expended on field work and crop production has an imputed value equal to the market wage for male laborers, and that all indirect labor inputs are attributable to women and children with a zero opportunity cost. We are now able to compare Bennett's net product figures which are based on a full imputation of family labor expended on bullocks, capital maintenance, etc. (the depreciation of farm-produced assets included in his "other type A costs") with the alternative approach. Using data for Uttar Pradesh which initially showed the small farms producing less net output (with more resources) than the largest farms, we now see a significant change (Table 2). Farm business income (the income from all family-owned

TABLE 2—DATA ON FARM BUSINESS INCOME AND NET PRODUCT—
UTTAR PRADESH, 1955-56
(Values in Rupees per Acre)

| 20 and over | 39.9 | 58 | 205 | 147 | 162 | 113.3 |

^a Includes all actual cash expenditures for seed, fertilizer, machinery, parts, total replacements, hired labor, land tax, irrigation charges, hired bullock labor, etc., plus "kind" expenses: crop retained for seed, animal feed, etc. Since we have a large sample, the annual purchases for tools, parts, etc. should approximate annual depreciation of purchased capital goods [4, p. 81].

^b Gross output minus cash and kind expenses. Total return to all factors owned by farm family, including labor.

^c Net value added (net product) equals farm business income plus payments in cash and kind to hired labor. Slightly understates net value added by not including very small interest charge on borrowed capital.

^d Bennett's net product, Table 2. It is lower than our net value added by depreciation charges for family labor contained in farm buildings, bullocks, etc.

Source: [4, p. 81], [6, pp. 817, 822].

factors including labor) which indicates the actual cash and produce available for consumption, is higher on the small farms. The important net product figures which measure the total welfare contribution of agriculture now are higher on the small farms and more in line with inputs and gross product (which is not a bad indicator of performance in the subsistence sector). This points to the conclusion that when we are dealing with farms which are in large part outside the market economy, the imputation problem is of central importance in evaluating comparable efficiency.

Finally, with reference to policy, Bennett seems overly bound by static functions and a conventional approach. I doubt that the larger Indian farmers, with the lowest average output per acre found anywhere, have rationally considered the return to additional capital investment and rejected it because of low expected yield. All the evidence indicates that a significant number reject offers of loans for seed, irrigation, fertilizer, and technical advice because they are satisfied with one crop a year dry cultivation [5, pp. 48-51]. On an above average size farm, the simplest method of cultivation will yield an adequate subsistence—by Indian standards. Not only is government investment needed to help shift agricultural production functions upward, but government land-tax and food-price policies must be revised so as to offer both pressures and inducements to the Indian farmers to respond to the output requirements of the market economy.

The Integration of Capital Budgeting and Stock Valuation: Comment

In a recent paper [4] Lerner and Carleton (hereafter L&C) attempt to integrate existing hypotheses of capital budgeting and stock valuation into one comprehensive theory. L&C's general idea is that this purpose can be achieved by replacing "the single-equation nature of recent capital budgeting and security valuation models" [4, p. 683] with a multiple-equation model. Their attempt should be welcomed, since such a general approach promises to be fruitful for further exploration into the theory of finance. Nevertheless, it is here suggested that L&C's model involves implicit as-

sumptions that are inappropriate for a general theory, and, moreover, owing to a technical error, the conclusions of their own model are misinterpreted.

L&C develop a two equation model. The first (equation 1.4) is a valuation function, and the second (equation 2.3) is an investment opportunities function. This model determines the optimal rate for two decision variables: the rate of return on assets and the earning retention rate which serves as a surrogate for the firm's investment budget. The optimal rates are defined as those which maximize the firm's market value.

The basic fallacy of the proposed model is that it is constructed to determine the optimal *average* rate of return rather than the marginal rate.¹ Since the average rate of return does not reflect the specific form of the investment-opportunities function, it is not uniquely related to the marginal rate. Thus the average rate is ambiguous and is, therefore, an inappropriate variable on which to base capital investment decisions. Moreover, such a model is liable to lead to misinterpretations.

One example is provided by L&C's conclusion that the optimal rate of return should in general be greater than the firm's cost of capital (k). L&C misinterpret this result: "This conclusion that firms should not in general invest until $r = \alpha/(1 - \psi)$ [or equivalently until $r = k$] is admittedly *at variance with traditional statements* on the subject" [4, p. 699, italics ours].

This statement should be challenged. L&C's optimal average rate of return is determined in a model based on a downward sloping investment-opportunities function. This in itself implies that the marginal rate is lower than the average rate. In order to maximize its present value the firm should invest—according to "traditional statements"—until the marginal rate of return equals the cost of capital. It follows, therefore, that the average rate of return is higher than the cost of capital.² Thus L&C's explicit conclusion does not vary with traditional theory.

Nevertheless, a rigorous analysis of L&C's model, which explicitly differentiates marginal from average rates of return, proves that the implied marginal rate is *lower* than the cost of capital. We now turn to the proof of this statement.

The valuation equation is given by 1.4' [4, p. 686]³ as

$$P_0 = \frac{(1 - b) Y_0}{k - rb},$$

¹ Although the rate of return is not explicitly defined in L&C's model our interpretation is implicit in equation 1.4' and the following text, [4 pp. 687–88]. Moreover, after defining the marginal rate of return (r') and the average rate (r) in connection with equation 2.3 [4, footnote 14, p. 695], L&C go on to state that "The reason for our formulation rests on the fact that (from the stock-valuation equation) r rather than r' is the focus of capital-budget decisions designed to maximize share price."

² In terms of the traditional theory the existence of investment opportunities with internal rate of return greater than the market cost of capital "means that adjustment to a competitive equilibrium is incomplete" [7].

³ L&C attribute this equation to M. J. Gordon [3, Ch. 4]. The equation was, however developed earlier by J. B. Williams [8, Chs. 6, 7]. Cf. D. Durand [2, p. 44].

where:

P_0 = the present market value of the firm.

Y_0 = the present annual earnings.

b = the earning retention rate, which serves as a surrogate for the investment budget.

r = the average rate of return on the investment budget.

L&C then substitute rA_0 for Y_0 (where A_0 stands for current total assets) to obtain equation 1.4'':

$$P_0 = \frac{(1 - b)rA_0}{k - rb}.$$

After assuming that r changes with b , they solve equation 1.4'' for r [4, p.688] to obtain equation 1.4''':

$$r = \frac{Pk}{b(P - A) + A}.$$

It should be emphasized that r , in the numerator of equation 1.4'', stands for the average rate of return on *existing* assets A_0 and is, therefore, a *constant* (hereafter marked r_0). In the denominator, however, r represents the rate of return on the current capital budget b , and is, therefore, a *variable*. Since L&C do not differentiate between the r 's in solving equation 1.4'', the solution they obtain for 1.4''' is invalid.⁴

The correct solution for r is⁵

$$(1.4^*) \quad r = r_0 \frac{A_0}{P} + \frac{1}{b} \left(k - r_0 \frac{A_0}{P} \right).$$

Both equations 1.4'' and 1.4* represent a family of iso-price hyperbolas which intersect the line $r=k$ at $b=1$. The two equations differ, however, in their asymptotes. L&C's curves (1.4''') all asymptotically approach the same horizontal line $r=0$, whereas the 1.4* curves do not all approach the same horizontal asymptote. For a given P the latter curve approaches the horizontal line

$$r = r_0 \frac{A_0}{P}.$$

The greater the value of P , the lower the asymptotic line.

⁴ $r_0 = Y_0/A_0$ by definition. Nevertheless, L&C substitute Y_0 of equation 1.4' by rA_0 instead of r_0A_0 [4, p. 687]. This slip is insignificant as long as r is a constant. It becomes, however, a crucial error at a later stage, when L&C make the assumption that r is a variable. Had L&C worked with the 1.4' version of the valuation equation, this error might be avoided automatically.

⁵ Or equivalently: $r = \frac{Y_0}{P} + \frac{1}{b} \left(k - \frac{Y_0}{P} \right).$

Given the investment-opportunities schedule, L&C find the optimal capital budget b from their tangency condition [4, eq. 2.6, p. 697]

$$\left(\frac{\partial r}{\partial b}\right)_{\text{eq. 1.4}'''} = \left(\frac{\partial r}{\partial b}\right)_{\text{eq. 2.3}}$$

Since 1.4''' is invalid, the proper tangency condition should be:

$$(2.6^*) \quad \left(\frac{\partial r}{\partial b}\right)_{\text{eq. 1.4}^*} = \left(\frac{\partial r}{\partial b}\right)_{\text{eq. 2.3}}$$

From equation 2.6* it follows that

$$(2.6^{**}) \quad \left[\frac{\partial(rb)}{\partial b}\right]_{\text{eq. 1.4}^*} = \left[\frac{\partial(rb)}{\partial b}\right]_{\text{eq. 2.3}}$$

at the point of tangency. Since

$$\left[\frac{\partial(rb)}{\partial b}\right]_{\text{eq. 2.3}} \equiv r'$$

is the marginal rate of return on investment it follows that at the point of tangency

$$r' = \left[\frac{\partial(rb)}{\partial b}\right]_{\text{eq. 1.4}^*}$$

The latter derivative is constant and equal to⁶

$$r_0 \frac{A_0}{P}$$

As we showed above,

$$r = r_0 \frac{A_0}{P}$$

$$^6 (1.4^*) \quad r = r_0 \frac{A_0}{P} + \frac{1}{b} \left(k - r_0 \frac{A_0}{P} \right)$$

$$rb = r_0 \frac{A_0}{P} b + k - r_0 \frac{A_0}{P}$$

$$\frac{\partial(rb)}{\partial b} = r_0 \frac{A_0}{P}$$

or equivalently:

$$\frac{\partial(rb)}{\partial b} = \frac{Y_0}{P}$$

represents the horizontal asymptotes of the hyperbolas given by equation 1.4*. These hyperbolas intersect the line $r=k$ at $b=1$ and, therefore, their horizontal asymptotes are lower than the line $r=k$. Thus, we can conclude that the optimal marginal rate of return on investment, implied by L&C's model, is lower than the cost of capital.⁷

Figure 1 summarizes our analysis. P_1 and P_2 represent the family of the iso-price hyperbolas 1.4*. $L_m C_m$ is the investment-opportunities function

FIGURE 1

which links the *marginal* rate of return on investment with the investment budget. LC is that same function linking the investment budget with the *average* rate of return, as employed by Lerner and Carleton [4, cf. n. 14, p. 695]. The figure shows that at the point of tangency the average rate of return is higher than the cost of capital. Nonetheless, the figure also shows that the marginal rate of return is lower than the cost of capital. The figure also implies that, as the investment-opportunities function moves upwards, the optimal average rate of return on investment may increase, while the optimal marginal rate of return declines.

These results can be explained, however, by the nature of the valuation equation 1.4'. It is there implicitly assumed that, as the firm increases its

⁷ This same conclusion was reached by D. Bodenhorn [1, p. 487] and J. Lintner [5, p. 302].

investments by raising the rate of retained earnings (*b*), the *future* investment opportunities increase proportionately and thus become more profitable.⁸ The increase in future profitability constitutes an additional (indirect) return which compensates the firm for the loss caused by the marginal investment. A correct definition of the marginal rate of return should include not only the direct return, as employed by L&C, but the indirect return as well. Once this is done, the marginal rate of return at the optimum is equal to the cost of capital, and thus "Lerner and Carleton's results are no longer inconsistent with the traditional theory."⁹ Nevertheless, since the particular dependence of future investment opportunities on the current capital budget has no general economic validity, it is questionable whether this valuation equation is appropriate for a general theory of finance.

The Integration of Capital Budgeting and Stock Valuation: Comment

In a recent article in this *Review* [2],¹ Professors Lerner and Carleton (hereafter L&C) state as perhaps the most important substantive conclusion of their analysis that "a firm should not in general invest until [the] internal rate of return equals the market discount rate" [2, p. 684]. They note that "this . . . is admittedly at variance with traditional statements on the subject" [2, p. 699]. We shall point out in this Comment that their

¹ L&C have used the same theoretical structure in two subsequent publications [3] and [4].

conclusion denying the validity of the traditional investment criterion seems to be incorrect. We shall also develop briefly the implications of a stock valuation model which we consider to be more useful for capital budgeting purposes than the constant growth model which they apply.

A basic difficulty in the L&C analysis is that the internal rate of return (r) is used in several different senses which are at times inappropriate to the analysis—a difficulty compounded by their use of a constant growth model. They use r at times as (i) an historic variable, $r = Y_0/A_0$ where Y_0 and A_0 are initial income and assets respectively. This ratio is given for any particular firm (though of course it may and does vary among firms) and cannot be affected by current decisions. At other times r is used as (ii) an average return on future investment. This return is relevant to future earnings growth and r is used in this sense when L&C express g , the assumed constant growth rate in dividends, as the product of r and b , where b is the fraction of earnings retained. In their general model, it is this r which they wish to optimize by appropriate decisions as to net investment per time period or in other words appropriate payout (and at times external financing) policies. Finally, r appears at times to be used as (iii) a marginal return on future investment. This again is a controllable variable depending on the size of future capital budgets. Clearly, r must be used in this sense when we consider the minimum rate of return which makes an investment project acceptable.²

In determining whether to accept or reject an investment proposal, indirect as well as direct returns on marginal investment are of course relevant. Current investment—in addition to the income stream which it generates directly—may open up the possibility of highly attractive future investment which would not have been feasible otherwise. To the extent that such investment opportunities are created, the value of the firm is enhanced, and current investment should be credited with an indirect return on this account in making the investment decision. However, there is no immediate contribution to earnings and asset growth related to this indirect return, so that in computing $g = br$ it is appropriate to use the (average) rate of direct return only.

The basic model L&C use for growth-stock valuation assumes that the rate of return is expected by investors to remain constant over time, the corporation is expected to retain a constant proportion of its income, all growth comes via retained earnings, and as a consequence dividends grow at a constant rate. If k is the market rate of discount, stock price (P_0) is initially expressed as

$$(1) \quad P_0 = \frac{(1 - b) Y_0}{k - rb}$$

² Unless Lerner and Carleton are thinking of r in this third sense, it is difficult to understand their assertions quoted at the beginning of this Comment.

or

$$(2) \quad P_0 = \frac{(1-b)rA_0}{k-rb}.$$

We prefer the first formulation since the second involves the assumption that the average return on future investment, the r in the denominator, is equal to the historic return Y_0/A_0 , the r is the numerator. For predictive purposes this may be a reasonable first approximation for many firms, though inappropriate for others; but for optimization purposes it is entirely unsuitable, unless in some sense we wish to solve for what the current yield on assets would have been if optimal decisions had been made through all past history.

L&C appear to have some difficulty in determining the optimum retention rate from these relationships by direct procedures, without recourse to a simultaneous equations approach. In their simplest case, where r and k are both taken as given and therefore independent of b , the difficulty vanishes when we observe that P is a substantially different function of b depending on whether $r=k$, $r<k$, or $r>k$, so that we must obtain separate solutions in each of the three cases. In the first case P is not a function of b at all and there is little point to computing a partial derivative with respect to b . In the second case it is a monotonically decreasing function of b and there is a well-defined corner maximum at $b=0$. In the third case there is a maximum at $b=k/r$, where price becomes infinite.

In the somewhat more realistic case where r is taken to be a (decreasing) linear function of b

$$(3) \quad r = \gamma_0 + \gamma_0\gamma_1 b, \quad (\gamma_0 > 0, \gamma_1 < 0)$$

the price function becomes

$$(4) \quad P_0 = \frac{(1-b)Y_0}{k - b(\gamma_0 + \gamma_0\gamma_1 b)},$$

by substitution in equation (1) above. Again there is no difficulty in determining the optimum retention ratio, though different solutions will occur in different regions of the $\gamma_0\gamma_1$ plane.

Assuming for convenience that k is determined independently of b and is greater than zero, the optimum retention ratio is zero when $\gamma_0 < k$, since in this case r in (3) can never exceed k for b in the relevant range. This is analogous to the case $r < k$ under the simpler assumption above. When $\gamma_0 + \gamma_0\gamma_1 > k$, an infinite price maximum results, since the denominator of (4), which is a quadratic function, must vanish for some value of b between zero and one. In this case, which is analogous to the case $r > k$ above, average return exceeds k even with 100 per cent retention.

However, for $k - \gamma_0\gamma_1 > \gamma_0 > -2\gamma_0\gamma_1$ it can readily be shown that a finite price maximum occurs. This condition simply implies that average return will fall below k with 100 per cent retention while marginal direct return will still exceed zero at that point. By setting the partial derivative of (4) with

respect to b equal to zero, we may determine the optimum retention ratio in this range:

$$(5) \quad b = 1 - \sqrt{1 + \frac{\gamma_0 - k}{\gamma_0 \gamma_1}}.$$

At this value of b it is quite true that the marginal rate of direct return, $\gamma_0 + 2\gamma_0\gamma_1b$, is lower than k . This is because two types of indirect return are rather artificially introduced by the special assumptions of the model used by L&C. First, in the absence of either external equity financing or increases in the debt-equity ratio, current investment is necessary to generate future retained earnings to take advantage of future high return investment possibilities. Second, and more basic, since average and therefore marginal r is assumed to be a constant function of b and not of dollars of new investment, the investment opportunities curve in terms of the latter must be shifting to the right over time for any $b > 0$, and in fact shifts faster the larger we make b , so long as the marginal direct return on investment remains positive.³ As time goes on, a given retention rate implies an increasing dollar amount of reinvested earnings, if b and r are both greater than zero. Thus the assumption that the average return, r , is a constant function of b means that a given r is obtainable on increasing dollar amounts of investment over time, and the higher the b selected the more rapidly will grow the dollar amounts on which that given r can be obtained (so long as each dollar reinvested yields some earnings growth). Hence current investment, in addition to providing an immediate and continuous direct return, provides an indirect return by causing the investment opportunities curve (defined in this context as a functional relationship between the volume of investment per time period and direct marginal return) to shift in a more favorable way over time than if the investment were not made.⁴

Once indirect return as well as direct return is considered, L&C's results are no longer inconsistent with the traditional theory. However, in our judgment the above considerations seriously prejudice the usefulness of the extremely popular constant growth model, at least as a device for determining the optimal retention ratio, though not perhaps for descriptive purposes when the retention ratio is predetermined. The dependence of future investment opportunities curves on the retention rate, particularly a dependence in which future opportunities are favorably affected by higher and higher

³ A similar point has been made by Merton Miller [5], in discussing the implications of a model presented by John Lintner.

⁴ In their May 1966 paper [4] Lerner and Carleton make the average return, r , a function of the growth rate of assets, rather than the retention rate. However, the implicit assumption that future investment opportunities are favorably affected by high retention rates is still present, since a time shift in the intercept of the rate of return schedule is posited, such that the sum of

$$(\alpha_0 - \beta_0)\lambda + (\alpha_1 - \beta_1)\lambda^2 A_t$$

plus the shift remains constant over time, where A_t is assets in period t , other symbols refer to constants, and $\alpha_1 - \beta_1 < 0$. As assets grow over time, larger and larger upward shifts are required each period and the higher the retention rate the more rapidly the required shifts increase [4, p. 211].

retention rates, is open to considerable question. Nevertheless, it is implicit in the assumption that a constant growth rate is attainable regardless of the (constant) retention ratio chosen.

The alternative assumption that the investment opportunities curve shifts over time in a manner independent of the firm's retention decision suggests an almost trivial solution to the retention decision under the basic assumption of a constant growth rate. Suppose that the curve shifts over time in such a manner that the dollar amount of investment bringing a given direct marginal return grows by a given percentage, say γ each year (based perhaps on the growth rate of the economy). Then b should be so chosen that the growth rate of investible funds and of earnings will equal that of investment opportunities or $br = \gamma$. This is in fact the only constant growth rate of earnings available to the firm under these circumstances and the only one which maintains a stable relationship of r to b over time.

Realistically, we would expect that certain investments will have favorable effects on future investment opportunities, but the magnitude of these effects will vary among investments and there is no reason to suppose that the aggregate effect will conform to the specifications of the L&C model, for an arbitrarily selected retention ratio.

It may be useful to demonstrate more directly that a stock-valuation formula can be combined with an investment opportunities schedule (and if desired with other relevant equations) without affecting the validity of the traditional theory. For this purpose it is desirable to introduce an alternative valuation equation which allows for the interdependence of investment decisions in a more explicit and flexible way than does the constant growth model. Then it can readily be shown (though in a sense the proposition is tautological) that value is maximized when marginal return on investment (direct plus indirect) equals the earnings capitalization rate, regardless of whether the profitability of investment in one period is or is not a function of investment in another period or whether the risk class of the enterprise is affected by new investment.

We shall assume a company has current net income of Y_0 which it would earn each year in perpetuity if it made no new net investments; plans to invest I_1 at the beginning of this year and I_2 at the beginning of next year on which it would earn r_1 and r_2 respectively in perpetuity; raises the necessary funds by issuing common stock at a "cost" of i which is equivalent to the capitalization rate on the old equity and pays out all net income in dividends.⁵ Then the current total value of the stock may be written as

$$(6) \quad S = \frac{Y_0}{i} + \frac{I_1(r_1 - i)}{i} + \frac{I_2(r_2 - i)}{(1 + i)i}.$$

Maximizing S with respect to I_1 requires $dS/dI_1 = 0$. For simplicity we shall assume $di/dI_1 = 0$ but, following L&C, we shall consider $r_j = f(I_j)$. The resulting equation is

⁵ The model, but not the analysis and conclusion, is essentially identical with that used by Diran Bodenhorn [1].

$$(7) \quad \frac{dI_1 r_1}{dI_1} + \frac{1}{(1+i)} \frac{dI_2(r_2 - i)}{dI_1} = i.$$

In other words, the direct marginal rate of return on I_1 plus the discounted indirect marginal rate of return must be equal to the capitalization rate at the optimum. If I_2 and r_2 are both independent of I_1 , the indirect return is of course zero. Similarly, if $dr_1/dI_1 = 0$, the direct marginal rate of return may be written as r_1 . However, the introduction of the functional relation between r and I or of interdependence among investment decisions does not affect the validity of the traditional investment criterion.

A change in the required rate of return on the company's shares as a result of new investment simply requires an allowance for another type of indirect return—i.e., the rate of return represented by the capital gain (or loss) per unit of investment as a result of the change in the capitalization rate. Thus, if we allow for a change in the capitalization rate as a result of a single new investment, the current value of stock may be written as

$$(8) \quad S = \frac{Y_0}{i} + \frac{I_1(r - i)}{i}$$

but now $i = F(I)$ so that $di/dI \neq 0$. Maximizing S as before, the resulting equation is

$$(9) \quad \frac{dI_1 r_1}{dI_1} - \left(\frac{Y_0 + I_1 r_1}{i} \right) \frac{di}{dI} = i$$

so that again the direct marginal rate of return on I_1 plus the indirect marginal rate of return (which is negative if $di/dI > 0$, with the rate of loss measured by the capitalized value of both old and new earnings multiplied by the marginal rate of increase in the capitalization rate) must be equal to the new capitalization rate at the optimum.

In concluding, we should like to question briefly the usefulness of the forms used by L&C to specify the very important functional relations (1) between the market rate of discount (or capitalization rate) and company growth in per share earnings [2, p. 690] and (2) between the rate of return and the retention ratio [2, p. 696]. The first implicitly assumes that the capitalization rate is equal to a constant plus a fraction of the growth rate, the second that the rate of return is a simple linear function of the retention ratio. Both assumptions seem tenuous to us. We doubt that all companies with zero growth expectations are regarded as being equally risky, while the rate of return is better expressed as a function of investment than of the retention ratio.⁶

JEAN CROCKETT AND IRWIN FRIEND*

* The authors are respectively professor of finance and professor of economics and finance at the Wharton School of Finance and Commerce, University of Pennsylvania.

⁶ Somewhat different assumptions are used in the May 1966 Lerner-Carleton article [4]. In addition to the different rate of return function discussed earlier in this Comment, the new functional relation between the capitalization rate and company growth is postulated to be linear in the variance of the growth rate rather than in the growth rate itself. This new assumption seems more plausible to us.

Reply

If we interpret the comments of Professors Crockett and Friend and of Ben-Shahar and Asher with respect to our 1964 [2] article correctly, their principal criticisms are directed to two related points: (1) an alleged failure to distinguish between a corporation's average and marginal rate of return;¹ and (2) an allegedly unreasonable assumption of a corporate profit opportunities schedule which is stationary through time.² These comments are constructive in that they require us to be more explicit in specifying our model than we were in 1964.

With respect to the first criticism, it is true that our model does call for the firm that strives to maximize shareholder wealth to select a target average rate of return on assets. Since we restricted ourselves to the case of a one-asset firm³ only one rate of return is possible for the firm in any given period. Our concern over the target average rate was dictated by the share price model itself, for when a person purchases a share of stock, he buys an expected average rate of return over an indefinitely long period. More importantly, the model referred to a firm's equilibrium position; hence it was possible to talk about the unique solution rate of return as if it lasted indefinitely into the future.

Both critics of our paper, however took us to task for not discussing the marginal r (which both believe in equilibrium will be less than k). The issue that must be raised before this problem can be discussed is "with respect to what is r marginal?"

The traditional capital budgeting approach answers the question by stating that r is marginal with respect to additional dollars of investment outlays. Since our price model postulates a constant growth rate as a variable, this approach will not do. Both critics assert that the r in the numerator of our valuation equation refers to a different time period (namely, historical) than the r in the denominator (future growth rate) of the equation.

¹ Vickers [6] has also suggested this criticism.

² In 1963, Lintner [1] suggested that for analytical purposes, it was convenient to think of a firm as having a stationary profit opportunities schedule. Miller's discussion [5] of this pioneering work raised some of the same issues underlying the two comments on our paper.

³ The implicit assumption of a homogeneous asset base, so that investments increase the scale rather than the diversity of the firm, is common to many articles in the field. See for example any of the several studies by Modigliani and Miller and [3], Ch. 4.

Hence, the r in the denominator may be marginal (or at least incremental) with respect to time. Since we describe a continuous and static equilibrium situation, for a one-asset firm, both of the r 's are equal in solution and invariant through time. The critics' assertions are thus inappropriate.

The issue of a marginal rate of return, however, can be examined in another context. If growth is defined as the product of two variables, r and b , and we ask "how does growth vary with b ," we find

$$(1) \quad \frac{\partial g}{\partial b} = r + \frac{dr}{db} b.$$

The first term on the right, r , our critics call the direct effect of the marginal rate of return; the second term, the indirect effect.

Our profit opportunities constraint (which we referred to as the LC function in our article) was specified as:

$$(2) \quad r = \gamma_0 + \gamma_1 b.$$

Obviously, if γ_0 of equation (2) corresponds to r of equation (1) and γ_1 of equation (2) to dr/db , our r is $\partial g/\partial b$. That is, the "marginal rate of return" or marginal growth rate with respect to changes in b , is simply the (unique solution) rate of return on assets as a function of b .

We have shown elsewhere [3, p. 136] that for a unique price maximization to occur, the specific form of the LC function depends upon the way the k function is specified. Hence more information is required before we can determine the variable that we want r to vary with. In the trivial case, when k is a constant, our specification $r = \gamma_0 + \gamma_1 b$ will satisfy the valuation model. In the more realistic case, when k itself is a function of the investors' alternatives and the riskiness of the firm, a more complicated profit opportunities schedule may be required to constrain the valuation equation. Specifically, if risk is measured by the variance of the firm's growth rate, under some conditions, a deterministic solution can be found if the profits opportunities function is specified as $r = \gamma_0 + \gamma_1 g$.

With respect to the second criticism, the specification of a time invariant profit opportunities schedule is, of course, necessary in order to be consistent with a constant expected growth rate share price model. By appealing to changes in national income or to changes in the prices of substitute and complementary products, the functions can plausibly be considered as stationary [3, Ch. 5]; also [4].

In a very general corporate financial model, it would be desirable to utilize time-varying profit opportunities and discount function. The appeal of such a model, however, is reduced by practical difficulties. Specifically, the solution to such an equation requires the use of the calculus of variations and we find time vectors of return, retention rates, and growth rates rather than single values. If an easier analytical method than this were found for handling the problem, a major breakthrough in the field could occur.

The Soviet Collective Farm as a Producer Cooperative: Comment

Professor Domar has set up a very strange model of an ideal cooperative farm.¹ A certain area of land is being cultivated by a group of workers and the net produce shared amongst them. They have to decide how much work to do. According to Domar, they choose to maximize the return per unit of work. He does not offer any explanation of why they should do so.

It would be more natural to suppose that they are interested in income per man year. To maximize income requires the marginal product per unit of work to be zero. The members of the cooperative may be supposed to prefer a smaller amount of work. If they are all alike, they can decide what is the marginal disutility of effort at various levels, that is, how much income an individual would forgo in order to do less than any given amount of work. They then fix the amount of work by the rule that marginal disutility is not greater than marginal product. If they all have different evaluations, some means has to be found to arrive at an agreed plan.

In the article by Benjamin Ward to which Domar refers the problem is different. A number of workers have been allotted a plant (on payment of rent to the state), and are free to regulate the numbers to which employment is offered. If the initial labor force (at the moment when this system is introduced) is less than that at which income per man is maximized, they recruit more colleagues, up to the point where marginal revenue is not less than marginal nonlabor costs. But if the initial labor force was larger than this, how are they to proceed? Income *for those that remain* could be increased by dismissing some. How do they choose who is to become unemployed or to seek work at a less prosperous enterprise?

¹ "The Soviet Collective Farm as a Producer Cooperative," *Am. Econ. Rev.*, Sept., 1966, 56, 734-57.

In setting up models of this type it is necessary to begin by asking the elementary economic question *cui bono*?

Reply

I fully share Professor Robinson's objection to the assumption that workers in a co-op would "choose to maximize the return per unit of work," and I said exactly that on page 742 of my paper. The exclusion of this assumption gave rise to the "Model with a Supply Curve of Labor" (pp. 742-47) which embodied the essence of the suggestion made in the third paragraph of her note. Hence its purpose escapes me.

Turning to another matter, I have been informed that I failed to acknowledge an important contribution to the theory of cooperatives by Professor Peter G. Helmberger, "Cooperative Enterprise as a Structural Dimension of Farm Markets," published in the *Journal of Farm Economics* in August 1964.¹ For that matter, a number of other papers on co-ops by Helmberger and others have been published in that journal (the latest appearing in the August 1966 issue). I have to plead guilty to having neglected an important periodical.

Returns to Scale and the Spacing of Isoquants: Comment

In a recent issue of this journal [1, pp. 501-5] A. M. Levenson and Babette Solon show the error in the usual textbook statement that greater (less) than unitary scale elasticity implies that successively numbered isoquants are getting ever closer (farther apart). A feature of their paper, which in no way detracts from the main results, is that the authors say "It is the purpose of this note to show (1) that isoquant spacing depends on marginal, not average, returns to scale; and (2) that the above usually stated relationships between average returns to scale and spacing of isoquants are accurate only for homogeneous production functions" [1, pp. 501-2], but their paper does not show how isoquant spacing depends on marginal returns to scale, nor does it show (2) which is, in fact, false. This comment is intended to supplement the Levenson-Solon paper by clearing up these two points.

To show the relationship between isoquant spacing and marginal returns to scale for a production function $f(K, L)$ it is convenient to express K and L in terms of $u = (K^2 + L^2)^{1/2}$ and $v = K/L$, the distance from the origin of, and the slope of the ray through, the point (K, L) .¹ Then marginal returns to

¹ The explicit expressions for K and L are $K = uv(1+v^2)^{-1/2}$, $L = u(1+v^2)^{-1/2}$ whence $f_u = f_K K_u + f_L L_u = (K^2 + L^2)^{-1/2} [K f_K + L f_L]$.

scale can be defined as $f_u(u, v)$ the partial derivative of output with respect to distance from the origin holding K/L constant. At (K, L) the distance, along the ray, between isoquants representing output levels c apart is determined by the solution for t of $f(u+t, v) - f(u, v) = c$ which, on taking differentials, yields the equation $(du+dt)f_{u+t}(u+t, v) - du f_u(u, v) = 0$, and so $dt/du = f_u(u, v)/f_{u+t}(u+t, v) - 1$. Since f_u and f_{u+t} are assumed positive for a production function this shows that $dt/du < 0$ or > 0 according as f_u is increasing or decreasing; so that, for sufficiently small c , whether or not isoquants representing output levels c apart are getting closer in the neighborhood of (K, L) depends on whether or not marginal returns to scale are increasing there. This condition, of course, also determines whether or not the vertical section of f by the plane through the ray with slope K/L is convex above that point.

With respect to (2) of Levenson and Solon's statement of purpose average returns to scale can be defined as $f(u, v)/u$ and the coefficient of scale elasticity, E , as $(u/f)f_u$, or marginal divided by average returns to scale. With v fixed, all these quantities are functions of u alone and by the well-known relation between marginal and average functions $E > 1$ (< 1) is equivalent to the statement that average returns are increasing (decreasing). Thus $E > 1$ (< 1) will imply that isoquants are getting closer together (farther apart) for any production function which is such that average and marginal returns always increase or decrease together, and only for such functions will these usually stated relationships hold. That such productions need not be homogeneous is shown by considering f of the form $R(K, L) + S(K, L)$ where R is homogeneous of degree one and S is homogeneous of degree $n+1$ (> 0). It is readily verified that this f is not homogeneous; and by using note 1 and Euler's theorem, that, for it, the rate of change of marginal returns to scale is $n+1$ times the rate of change of average returns to scale so that these will always move in the same direction and the usually stated relationships will hold.

F. W. McELROY*

BOOK REVIEWS

General Economics; Methodology

On Political Economy and Econometrics: Essays in Honour of Oskar Lange.

No editor listed. Warsaw, Poland: Polish Scientific Publishers, 1965;
New York: Pergamon Press, distributor. Pp. viii, 661. \$18.50.

This volume began as a *festschrift* celebrating Lange's sixtieth birthday and ended as a *festschrift* in memoriam. In either case, it is not a suitable testimonial to a person of the intellectual power Lange exhibited in the 'thirties and early 'forties. Indeed, it is doubtless the worst *festschrift* ever published; and unless standards degenerate markedly, it will maintain this rating throughout all time. This is a pity; but the greater pity is that if one judges by the copious citations to Lange's recent work, Lange himself would not agree.

The reader gets a foretaste of what is to come on page one: "The crucial moment of his [Lange's] life came in 1918. On the occasion of the hundredth anniversary of the birth of Karl Marx, the fourteen-year-old boy gave . . . a lecture on Marxism. In the autumn of that year he took part in disarming the Germans, . . . immediately established contact with the Council of Workers' Delegates, . . . organized a circle of the Union of Polish Socialist youth," all the while reading Marx, Engels, and Kautsky and studying anthropology, history of religions, sociology, mathematics, and comparative linguistics. Add a little thinly disguised sex and one has an adolescent Helen MacInnes hero.

Naiveté and nonsense do not end here, however. P. Baran and P. Sweezy inform the reader that the U.S. economy became stagnant after World War II (p. 16); that bourgeois economics can be divided into two parts, each of which clearly shows "how developing contradictions in the economy itself call forth corresponding contradictions in the realm of theory" (p. 18); and, most surprising, that J. K. Galbraith "turns out on careful inspection to be the most enthusiastic apologist for a society dominated by *big* business" (p. 29).

This is not all. M. Kalecki tells the reader that historical materialism is a generalized econometric model; A. A. Konius that marginal utility theory confirms the theories of Marx; Kuczynski that a decrease in variable capital in the United States is connected with "the parasitic tendencies of capitalists while in socialist countries . . . [it] leads to a more rapid growth in gross total product"; März that Nietzsche was a dominating influence on Schumpeter; Mrs. Robinson that "market research in a capitalist world is directed to finding out how to bamboozle the housewife"; and Singh that "co-existence alone could help the Soviet oasis to survive in the capitalist desert." That's the way it goes with dispassionate rationality.

Things are not as bad as they seem; but they almost are. Some useful summaries of research, mostly their own, are given by R. Frisch, P. C. Mahalano-

bis, F. Perroux, K. Rothschild, R. Stone, J. Tinbergen, and G. Tintner. Neyman contributed an interesting, brief history of behavioristic views in regard to mathematical statistics. And, by alphabetical coincidence, the best was saved for last. The papers by A. Wakar, J. G. Zielinski, and L. J. Zimmerman are real contributions to the problems they tackle.

The price of the book itself should limit its audience. I would personally recommend its purchase only to those who delight in twice-told tales and thrice-told dogma.

**Price and Allocation Theory; Income and Employment Theory;
Related Empirical Studies; History of Economic Thought**

The Nature of Economic Thought. By G. L. S. SHACKLE. New York and Cambridge: Cambridge University Press, 1966. Pp. xiv, 322. \$9.50.

This is a collection of essays and reviews written by Professor Shackle between 1955 and 1964. Their topics vary considerably, but they are all distinguished by the author's pleasing style and frequently delightful turns of phrase and by his constant preoccupation not so much with the general "nature of economic thought" as with the philosophical riddle of how freedom of choice fits into a determinate world.

Most economists are prepared to liquidate the puzzle by granting that however strongly a man feels his freedom to choose among several possibilities of action, and however keenly he suffers all the agonies and ecstasies of conscious decision, from an outside point of view his choice must be seen as the determinate resultant of the characteristics of the chooser and the conditions under which he has to choose. Economists have indeed contributed to the philosophical understanding of the subjectivity of freedom by showing how all the economic subjects taken together are forced, by changes in their incomes, to choose freely to save just the amount that the investors are investing (while the investors are forced, by induced changes in their inventories and profit expectations, to choose freely to invest exactly as much as the savers are saving).

It may be impossible, or even demonstrably impossible, for anyone to know enough to be able to foretell with certainty an individual's choice, or indeed any future outcome, in our complicated universe. But the seeker for understanding must everywhere look for conditions which determine outcomes, and there is not much point in discussing whether those that will never be discovered *really* exist or not.

Shackle however refuses to dismiss freedom of choice as a subjective illusion. He insists that there *must* be some real freedom because he feels it. Furthermore if it is known with certainty that one course of action is definitely better than all the others there is again no real alternative and no real choice. Real choice is possible therefore only where there is uncertainty. Yet the traditional theory of probability provides no comfort for Shackle because it can

be applied only where the alternative possibilities, like the six sides of the die, are all known. Real freedom of choice involves the ability of the subject to *create* new courses of action (with new outcomes) which did not exist and certainly were not known before he invented them. A new world is continually being created which cannot be included in any previously existing closed set of possibilities and which is therefore not amenable to the probability calculus.

J. W. Dunne, once impaled on the same philosophical dilemma by a theory that dreams foretell the future and thus permit the future to be altered (by the avoidance of foretold calamities), was forced into a theory of a serial universe with infinitely manifold futures (*An Experiment with Time*, New York, 1927). Shackle seeks a less dramatic way out. Since men must act long before they can make rational calculations of the probabilities of all possibilities, he supposes that the decision maker considers only *possibilities* and focuses only on the best and the worst possible outcomes in choosing among alternative courses of action. This would seem no worse a simplification than to suppose that he decides on the basis of the actuarial value of each alternative, or even this together with some measure of the variance of the probability distribution; and it is definitely better than the assumption that he merely minimizes his maximum possible loss (i.e., with no regard to the possible gain). But Shackle recognizes that some possibilities seem more remote than others and can have little influence even if they involve extreme gains or losses. He therefore has the chooser *weigh* the possible gains or losses by the inverse of the "potential surprise"—the degree of surprise that the subject thinks he would feel if that outcome materialized. If a possibility is "hardly possible" and so would surprise him very much if it occurred he will give it very little weight, equating it to a smaller "standardized" gain or loss with zero potential surprise, being "perfectly possible."

This reviewer, having lost interest in the philosophical conundrum, is unable to distinguish between the "degree of potential non-surprise" and (subjective) probability, or to see why the sum of probabilities cannot always be made to sum to unity by adding the probability of "some other outcome" to those envisaged, or indeed why one need be concerned with such summation of probabilities. Consequently it seems to him that Shackle's troubles arise only from taking too seriously the apparent denial by certain probability theorists of the meaningfulness of subjective probability when they say that probability cannot be applied to *unique* events. Every actual decision constitutes a unique event and has a unique outcome—not a probable distribution of possible outcomes. (Even for an insurance company each issuance of a policy is a unique event and definitely will or definitely will not be followed by a claim.) What is not meaningful is the *frequency* of a unique event, but that is perhaps too obvious a statement on which to build a school of thought without confusing the issue by calling frequency "objective probability." Probability plain is meaningless when applied to *events*. Events don't have probabilities. They either happen or don't happen. Probability plain is meaningful only as a subjective feeling. It indicates the degree of a subject's ignorance of how things will turn out, and its "improbability" can very well be measured by "potential surprise." (This by no means questions the theory that potential surprise is

strongly influenced by knowledge of the *frequency* of such outcomes in similar situations.) Furthermore, the use of this measure or description of probability in no way necessitates any concern with the free will paradox.

Shackle's unorthodox terminology has in turn been taken too seriously by critics of his work and this has distracted economists from his positive contribution of interesting suggestions on the nature of some of the shortcuts that may be taken by men who have to make decisions.

The frequency model for explaining probability is not the only model that Shackle has taken too seriously. In one paper ("The Economist's Model of Man," p. 123, unfortunately directed to noneconomists), he takes too seriously the model of economic man in a perfectly competitive economy and is moved to some Veblen-like mocking of this oversimplification. (An oversimplification is after all only a simplification taken too seriously.) In another essay ("Resources and Demands," p. 189) he apparently takes too seriously the only too common economic illiteracy of social critics and goes to the other extreme of a Bastiat-like panygeric to the marvels of the price and market mechanism as a giant computer that gives everyone "his due" (p. 192, even while himself oversimplifying the description of the computation by supposing the computer to be fed on simple demand curves, i.e. neglecting the effects of the prices of other goods on the amount of a good demanded).

But now I am myself guilty of unjust oversimplification. The extravagances I have just mentioned are largely justified and corrected in their context. While there are many minor points one can pick a quarrel with, there are also some intriguing puzzles and many illuminating suggestions.

I was annoyed, for example, to find clear diagnoses of both cost inflation and of demand inflation followed by prescriptions for only the latter, or by some hints that suggest, if only very faintly, that a little inflation is as bad as or worse than a little unemployment or that unnecessary government spending is more harmful or more prevalent or more in need of criticism than unnecessary private spending.

I was puzzled by his enthusiasm for a metaphor, from Artilochus via Isaiah Berlin, "The fox knows many things but the hedgehog knows one big thing" (pp. 16-32, 297), and by his ability to see in the hedgehog "the seeker after one sole all-encompassing Principle of Nature" (p. 30). But perhaps that is because I have less faith in the existence of any such Principle of Nature than in the Postulate of the Scientist (that there is order in nature) which has enabled him to get to know "many things."

I was delighted by many flashes of insight and felicities of expression, e.g., by the definition of money as the "total amount of payments [that] could be made *simultaneously*" (p. 196) or the beautiful delineation of an example of the very oversimplification I have belabored in this review when he says of the "period of production" that "The Austrians were too profound in elaborating their theory and the English too fastidious in criticising it" (p. 289). An important and very useful part of the book is Shackle's survey "Recent Theories Concerning the Nature or Role of Interest" (pp. 225-81, from the *Economic Journal*, 1960) which is relatively free from the leitmotif of the implications of freedom of choice. The book concludes with three interesting book reviews

written with such typical charming gentleness that one almost fails to notice it when Shackle charges the author with missing the main point and flying off in the wrong direction. The review of Kaldor's two volumes of essays, a fascinating collage of sentimental memories of thirty years of economic discussions, ends with "What an item for inclusion in that list of 'books I would take to a desert island'!" I would not put *The Nature of Economic Thought* in that category but I unhesitatingly recommend it (to economists) as excellent evening reading for profit with pleasure.

ABBA P. LERNER

University of California, Berkeley

A Keynesian Theory of Employment, Growth and Income Distribution. By SIDNEY WEINTRAUB. Philadelphia: Chilton Books, 1966. Pp. x, 147. \$7.95.

Much of recent growth theory is concerned with the following question: What must the path of the main economic variables through time be in order that the economy be in equilibrium at each moment of time? The answer, among other things, depends on initial conditions and so we may think of many equilibrium paths for an economy. Sometimes it can be shown that all such paths approach a particular one—usually the steady state path. One of the conditions of equilibrium is the fulfillment of expectations. It is clear that when we have discovered these questions we still have a long way to go before we can pretend to understand actual paths. In particular the actual behavior of effective demand through time as opposed to its behavior imposed by an equilibrium requirement needs attention. Similarly the present habit of taking "full employment" as one of the equilibrium conditions is limiting and certainly not "Keynesian."

Professor Weintraub's book is no doubt motivated by these deficiencies of present theory. It is my sad duty to report that he has not succeeded in remedying them. This is partly due to his quite imperfect command of what has already been achieved in this field, partly by his inability to distinguish identities from equations, and partly to the fact that, in the event, he too only considers equilibrium paths, except for some *obiter dicta*.

After a brief run through Harrod-Domar and "all that," Weintraub decides to investigate the theory of growth by means of schedules of aggregate monetary demand and supply. The schedules intersect at a moment of time and they shift through time. The monetary supply schedule is simply the money proceeds producers must expect in order to employ a certain amount of labor. It is equal to their production cost plus markup. For much of the analysis money wages are taken as fixed and the ratio of gross profits to wage payments assumed constant. The monetary demand schedule is made up of consumption demand (different propensities for wage earner and "others"), investment, and government. All systems are now at "go." Through time the intersection of the two schedules shifts. Evidently it can shift in a wide variety of ways. Relentlessly Weintraub pursues them all by means of an abundance of quasi-elasticities. If, for instance, as between two intersections money

proceeds have risen by a greater percentage than employment has, then the "Growth-Proceeds Elasticity" is greater than one. Since money wages are constant the truism that the share of wages declines follows—it is only another way of stating it. Then if we divide the equilibrium percentage increase in proceeds by the equilibrium increase in the value of capital we get the "capital-proceeds" elasticity. There are others. We can imagine umpteen combinations as well as the further amusing eventuality of these "elasticities" increasing or falling through time. At each stage the careful arithmetician will arrive at the correct answer—the economist may sleep awhile. For what is the point of this dreary catalogue of possibilities even though some are given economic names such as "capital-saving or capital-using," etc.? If the intersection points move in some particular fashion then they move in that fashion and we can leave it to the schoolboy to draw the arithmetical conclusions. What we want to know is: what makes the economy move from intersection point to intersection point, how do *relative* prices of inputs change, how are techniques chosen, how are expectations formed, what determines the innovations adopted, etc.? Weintraub allows only of passing references to some of these questions, and some he does not mean seriously, e.g., the suggestion that the "stability" problem here is like a cobweb"! The funny thing is that Weintraub knows what he is doing. Thus on noting the difficulties of analyzing technical progress in real economies he remarks: "Since our growth equation runs in terms of proceeds, investment ratios and capital-proceeds ratios, technical progress will not alter the truistic nature of these relations" (p. 119).

Although all sorts of other contingent matters are discussed, Weintraub continues his confusion between arithmetic and economic theory. I give only two instances. On relaxing the assumption that money wages are constant but retaining the assumption of a constant percentage markup on wage costs, he notes that if money wages rise by x per cent and employment and output remain constant, then money profits will rise by x per cent. He calls this "a conclusion of prime importance," and *deduces* that "money wage changes are probably the prime mover in profit changes" (p. 55)! Again starting with the identity: sales of consumer goods equal to purchases of consumer goods, he then implicitly assumes that purchases are equal to *ex ante* consumption outlays and on substitution into the identity arrives at what he calls an "equation which should be of major significance in price level theory" (p. 112)! One could continue almost indefinitely.

Weintraub occasionally makes general remarks on the nature of society. Here is one: "The distinctive feature of a capitalist economy is that wage earners are hired and paid a money wage" (p. 53). His references are largely to himself and to Mrs. Robinson whose preoccupation with the subtleties of economic choice or with the problems of capital valuation are however well beyond the author's reach. His interpretation of the meaning of $C_r \rightarrow 0$ in the Harrod equation is a classic in the misunderstanding of limits.

The book concludes with a chapter on optimum growth which largely says that since valuation of consumption at different moments of time depends on who is doing the valuing we cannot speak of "the" optimum growth rate.

There is no discussion either of efficient accumulation or of the necessary conditions for optimum accumulation under any given valuation.

F. H. HAHN

Churchill College, Cambridge

On the Theory and Measurement of Technical Change. By MURRAY BROWN. Cambridge: Cambridge University Press, 1966. Pp. xii, 214. \$8.50.

This study presents a theoretical analysis of technical change, a method for measuring neutral and non-neutral technical change, and an empirical application. Part I presents the theoretical analysis. The author is to be commended for bringing together: (1) a discussion of the concept of a technology; (2) a discussion of the characteristics of both the Cobb-Douglas and CES production functions; (3) an analysis and comparison of embodied and disembodied technical change; and (4) a particularly valuable discussion of short-run, long-run, and secular production functions, providing considerable insight into the dynamics of a changing technology. Unfortunately, this section, while of considerable interest, is unnecessarily vague and somewhat fuzzy, and is based on assumptions many of which are not made explicit.

Part II is concerned with the measurement of technical change, and builds on the theoretical work in Part I. The author reviews four methods that have been used: (1) the productivity ratio method, (2) the Solow method, (3) the Salter method, and (4) a method (used by Tinbergen) based on estimating Cobb-Douglas coefficients, assuming exponential, neutral technical change. The author then presents an ingenious method for measuring both neutral and nonneutral technical change. This method is based on the identification of technological epochs during which no non-neutral technical change occurs. Within each epoch, Cobb-Douglas coefficients and the ratio of neutral technical change are estimated.

Changes in the estimated coefficients from one epoch to another provide evidence on nonneutral technical change. More generally, interepochal differences in output are decomposed into (1) increase in inputs; (2) neutral technical change, and (3) nonneutral technical change.

There is some discussion also of the measurement of technical change in a CES world, but the subsequent empirical work is based on the Cobb-Douglas function.

The empirical application, presented in Part III, is based on the private domestic nonfarm sector of the U.S. economy for the period 1890-1960. Epochs are identified, and the parameters for each epoch are estimated. The principal results can be stated: (1) There were increasing returns during the first epoch (1890-1906), and decreasing returns thereafter. (2) There was a large increase in the use of labor-using techniques between 1939 and 1948. (3) There is evidence of large-scale structural change over the period 1890-1960. (4) The importance of technical change in raising output is a recent phenomenon: apparently the contribution of technical change increased sharply toward the end of the period studied.

There is an interesting discussion of the effect on employment of (1) techni-

cal change, (2) substitution of capital for labor, and (3) increases in output. The author notes that labor displaced by technical change has been absorbed by rising output. But this does not tell us a great deal about the underlying forces, which can be studied only at a much less aggregative level. Technical change in the widget industry may reduce the labor cost of producing a given number of widgets. If the demand for widgets is sufficiently inelastic, the result will be a reduction in employment in the widget industry. If, on the other hand, the widget demand curve is sufficiently elastic, then employment in the widget industry will rise. The net effect will depend on the biasedness of the technical change and on the elasticity of demand for widgets. For economy-wide technical change, the employment effect will depend on the biasedness and on the distribution among industries with differing elasticities of demand. Brown's discussion of this point is at times tautological, at times mystical, and does not appear to get to the heart of the matter.

Murray Brown has brought together a great deal of relevant material on technical change. The empirical work is of particular interest. However, the opaqueness of the theoretical sections detracts somewhat from the value of the book.

BENTON F. MASSELL

Institute for Development Studies, University College, Nairobi

Introduction to Price Theory. By MICHA GISSER. Scranton, Pa.: International Textbook Co., 1966. Pp. ix, 325. \$7.50.

The Market System. By ROBERT H. HAVEMAN AND KENYON A. KNOPF. New York: John Wiley & Sons, 1966. Pp. xiv, 223. \$1.95.

Introduction to Price Theory by Micha Gisser and *The Market System* by Robert H. Haveman and Kenyon A. Knopf are both microeconomic theory textbooks, but despite their similar content, they are intended for different readers. The former is appropriate for an intermediate level course while the latter is one volume of an introduction to economics series.

Introduction to Price Theory examines the conventional price theory subjects (demand and utility theory, theory of production, perfect competition, theory of supply, monopoly and imperfect competition, the labor market, and distribution theory), and, in addition, chapters entitled "Indirect Taxes" and "Price Theory as Applied to Agriculture" (Chs. 10 and 11, respectively) deal with specific applications. Gisser states in the preface that ". . . every effort has been made to present the basic elements of price theory by using simple tools such as tables and diagrams" (p. vii). He has been exceptionally successful in achieving this goal without sacrificing rigor. His lucid presentation is enhanced by including many numerical examples and by supplementing most chapters with appendices which contain the more difficult analytical concepts. There are instructive exercises at the end of each chapter, and the answers to numerical and "true-false-uncertain" questions are provided. Another excellent feature is the inclusion of a concise mathematical appendix (pp. 293-321) which will be appreciated by the more mathematically oriented students and teachers.

Gisser concludes with a somewhat disappointing chapter entitled "Capital

and Interest" (Ch. 15). As he states, "There are many approaches to the theory of capital. Since we do not want to provide the student with an encyclopedia in price theory, we had to select only one approach. We shall follow the theory of capital as formulated by Frank H. Knight and Milton Friedman" (p. 270). He therefore distinguishes human factors of production from "tangible capital" or all nonhuman factors of production. One unit of "*tangible capital*" is defined as a "complex of physical capital" capable of producing a net income flow of one dollar per unit time (pp. 272, 274). While this approach to capital theory is useful for some purposes, it does not, in my opinion, provide the student with an adequate introduction to economic models containing many *physically different, heterogenous* capital goods. For example, there is no reference to own-rates of return, which play an important role in models of economic growth and in the problem of efficient capital accumulation.

The book suffers from two deficiencies; the entire subject of general equilibrium is omitted, and there is only a superficial treatment of stability (pp. 143-45) in which no mention is made of the Walrasian, Marshallian, or Hicksian stability definitions.

Nevertheless, *Introduction to Price Theory* merits consideration by anyone teaching intermediate microeconomic theory.

In seven chapters *The Market System* provides an introductory level discussion of the economic concept of scarcity, supply and demand, consumption theory, supply and theory of the firm, the functioning of a competitive price system, imperfect competition, and welfare economics. Knopf, also editor of the series, explains the reason for an introductory text devoted exclusively to microeconomics:

Teachers of introductory economics seem to agree on the impracticality of presenting a comprehensive survey of economics to freshmen or sophomores. Many of them believe there is a need for some alternative which provides a solid core of principles while permitting an instructor to introduce a select set of problems and applied ideas. This series attempts to fill that need and also to give the layman a set of self-contained books that he can absorb with interest and profit, without assistance.

By offering greater flexibility in the choice of topics for study, these books represent a more realistic and reasonable approach to teaching economics than most of the large, catchall textbooks. With separate volumes and different authors for each topic, the instructor is not tied to a single track as in the omnibus introductory economics text (p. v.).

The Market System is consistent with this teaching philosophy; it offers a concise introduction to microeconomic theory in a comprehensible manner. It is well organized, and theoretical ideas such as indifference curves and marginal cost are carefully explained. A conclusion or summary is given at the end of each chapter, and numerical examples, tables, and graphs are instructively employed, but their use is not excessive. The book exhausts the list of appropriate introductory microeconomic topics with one exception; capital theory is completely neglected (present discounted value is not even mentioned), although perhaps this subject is scheduled for inclusion in another volume of the series.

"The Models and the Real Economy: Problems and Prospects," the concluding chapter (Ch. 7), warrants special attention. It is an unbiased and comprehensive introduction to the complex economic and ethical issues concerning efficient allocation of resources and social welfare both in a perfect competition model and in the real world. The existence of market power over supply and demand, frictions and uncertainties, immobilities, indivisibilities, and nonmarketable public goods are all discussed, and it is observed that perfect competition may result in an unethical distribution of income. Thus the authors make an excellent case for their conclusion that "Because of these qualities, the price system, by itself, cannot provide for maximum social welfare. It must be supplemented with other systems of social choice" (p. 217). This chapter makes excellent supplementary reading for *all* students of introductory economics.

EDWIN BURMEISTER

University of Pennsylvania

National Income and Employment Analysis. By ARNOLD COLLERY. New York: John Wiley & Sons, Inc., 1965. Pp. xiv, 154. Paper, \$1.95.

Unlike many recent publications in similar formats, the purpose of this book is to supplant rather than supplement conventional texts. Many will find it offers a worthwhile pedagogical improvement over the macro sections of the integrated hardbound texts designed for elementary economics courses. The first five chapters develop the simple Keynesian model and its implications for monetary and fiscal policy. The final two chapters explain the possible undesirable side effects of the Keynesian "medicine" for full employment: price instability and balance-of-payments problems.

By intent, the scope of the book is, at most, equal to analogous sections in standard texts. Some instructors may therefore indict the book for sins of omission, although these should generally be considered minor ones which are easily remediable in lecture. Collery's explicit intention was to strip away some of the less important techniques and details which, he feels, detract from a student's understanding and retention of the more crucial lessons to be drawn from macro theory. This is not to suggest, however, that the material which survived the pruning process is necessarily the easiest nor that the discussion does not attain a sophistication which is quite commendable at this level.

Collery's step-by-step elaboration of Keynesian national income analysis is, for the most part, a model of clarity and common-sense logic. For instance, his use of simple examples results in a strikingly clear and effective explanation of the "why" of the fundamental Keynesian equation. By consistently exercising care to present the student with the common-sense rationale of each succeeding proposition, he makes light work of frequently sticky points such as the passage from tautology to equilibrium equation wherein one must distinguish between the *ex post* and *ex ante* equality of savings and investment. A set of questions is appended to each major proposition developed in the text. These should be extremely useful for pedagogical purposes since they eschew

"cleverness" in favor of a direct but thorough illustration of the principle involved.

The exposition is so well formulated that little or no lecture time ought to be wasted in clearing up difficulties for the average student. With the essentials disposed of, an instructor would be relatively free to fill out the course according to his personal disposition, with institutional, theoretical, or practical refinements which the book itself does not seek to provide. This is a high recommendation for a book.

Collery does leave some points to quibble about, of course. His relatively muddy explanation of the balanced budget multiplier might easily have been improved by an algebraic proof similar to those used in other sections. The volume's simplistic statement of the "laws of consumption" will never cause a student to appreciate just what a disappointingly elusive animal "the" consumption function proves to be when we attempt to give it empirical content. The discussion of labor productivity in the inflation chapter reinforces rather than corrects the error of defining this concept in average rather than marginal terms. Still, such peccadilloes do not seriously mar a book which stands up conspicuously well as judged by the standard of its competition.

In evaluating any book of this type for classroom use, it is essential not to lose sight of its basic role as part of a "package." Collery's book represents an improvement on the corresponding segment of a hardbound text, but its usefulness is conditioned by the acceptability of similar material which supplants the remainder of the orthodox Principles text. Even at its modest price, it would be difficult to justify the book's adoption for *joint* use with a standard text since it does not supplement such texts in any meaningful sense.

CHARLES J. GOETZ

University of Illinois

Economic Analysis of the Firm: Theory and Practice. By IVORY L. LYONS AND MANUEL ZYMELMAN. New York and London: Pitman Publishing Corp., 1966. Pp. xii, 422. \$8.75.

Teaching microeconomics to undergraduates in business can be a most frustrating experience. Many faculty members in a typical business school, as well as the students, want a course which is practical and filled with examples. Economists, on the other hand, often find little advantage in offering such a course and end up by offering a course in microeconomic theory. There have been a number of attempts to write a text for such a course, but there have been relatively few that have satisfied either group.

The authors of the present work have attempted to bridge the gap between theory and practice by first explaining the theory and then using problems or cases to permit the student to extend the analysis beyond that in the text. The cases include simple problems in computing marginal revenue and marginal cost, antitrust cases, the Kennedy-Steel controversy, and many others. The theory which is included is fairly standard with the exception of that of the last chapters where the authors take up investments, forecasting, and simple statistical techniques.

Unfortunately, however, the errors committed by the authors in their exposition of economic theory overwhelm the rest of the book. Such errors as "AFC is the slope of a line drawn from the origin to a point on TC" (p. 59); the industry demand curve and the firm demand curve have the same slope under pure competition for it is just the difference in scale which makes them appear different (p. 125-26); a rising average product curve when the marginal product curve is below the average (p. 271); the assertion that the monopolist can set either price or quantity but not both (p. 146); crediting increasing returns to scale to improved production methods (p. 66); the explanation of profit maximization (p. 82); and many, many others all serve to discredit the book.

But it is not only a matter of errors. In many places, the exposition is so obscure that it is difficult to determine what the authors have in mind (for example, the discussion of long- and short-run costs on pages 62-63); diagrams are not well placed in the texts and many diagrams are such a maze of lines that they are difficult to understand; many essential explanations are either omitted or superficial; and though the authors have included a mathematical appendix, there is no attempt to use calculus at points where it might well be used; and what mathematics is used is rather laborious.

In short, this book has nothing to recommend its use as a text.

Growth and Welfare in the American Past—A New Economic History. By DOUGLASS C. NORTH. Englewood Cliffs, N.J.: Prentice-Hall, 1966. Pp. xiv, 210. \$5.95; paper, \$2.95.

"A primary objective of this book," Professor North tells us, "is to present a nontechnical appraisal of America's economic experience, weaving together the summary results of our new quantitative knowledge of America's past with reappraisal of a number of basic issues and interpretations." What follows is the first attempt to apply the "new economic history" to U.S. development as a whole, from the Colonial period through 1945-65. The fourteen chapters include "Theory, Statistics, and History" (Ch. 1), "An Overview of the Development of the U.S. Economy" (Ch. 2), and twelve more arranged in a general chronological order grouped about specific, and often conventional, topics. They are concentrated in the period up to World War I; only the last two chapters, and small parts of the second, deal with the post-1914 years.

As North has defined it elsewhere, the new economic history is aimed at a reconstruction of the U.S. experience, "firmly grounded in statistical data . . . [which will provide] the quantitative information necessary to outline the contours and patterns of American economic change from the past." The ultimate product will be a "cumulating number of analytical insights into the

process of past economic change which are the essential prerequisite to evolving sound theoretical propositions about long-run economic development." (This *Review*, March, 1963, 53, 129-30.)

The school of economic history has been subjected to criticism from several quarters in recent years. While some of the complaints have merit, others have been unfair and irrelevant. To help resolve at least some of these doubts, it would seem all the more imperative for new economic historians to build analytical frameworks upon which the elements of their work can be grafted, and given meaning. No one has been more insistent on this point than North himself; *The Economic Growth of the United States, 1790-1860* sets a worthy example. Disappointment is thus compounded when his latest book suffers from lack of a clear theoretical structure—it tries to blend several approaches principally, but not exclusively, quantitative.

Economic theory and statistics can be applied to history in two basic ways: (1) by study of the macro- and microeconomic variables constituting the dynamic forces in economic growth, their trends through time, and the interactions among them; and (2) through use of economic theory to analyze more familiar historical topics, events, and institutions. Both approaches are covered by the theoretical discussions in Chapter 1 (pp. 3-11, 12-14). Someday it may prove possible to unify the two around the axis of quantitative measurement and inference, but North's present effort does not appear to result in a happy marriage.

The body of the first approach is tightly wedged into Chapter 2 (the "overview"), in which all bases are touched: output and output per capita, population and immigration, labor force composition, the rural-urban shift, transport costs, banking institutions, foreign investment, internal migration, business cycles, and corporate structure. The second approach is found throughout the book; it tends to develop into a pattern of confrontations with disparate issues, many of which are constructs of the more traditional historians. The overall effect is noticeably uneven.

This book is meant for the student, the uninitiated, anyone who might want to introduce himself to the new economic history. Yet I wonder what impressions such a reader would get. The essence of the quantitative approach to U.S. growth—the role of the market and the parametric function of its price system—would probably escape him in the woods of Chapter 2; and other sections of the book might too readily lead him to conclude that economic history involves employing deft statistical techniques to answer, more or less, a series of propositions that historians have posed for us down through the years. This latter fear is reinforced by stretches of the book that turn into accounts of intramural debates among economic historians. By no means do I downgrade the importance of these dialogues; I simply question whether a nontechnical appraisal is the place for them and whether much is accomplished by paying them respect in such truncated form.

These are some of the problems created by *Growth and Welfare*, and they make it appear that the audience for which it is intended will benefit less than North had hoped. More likely to benefit, though, will be the reader with a cer-

tain amount of knowledge about the new economic history before taking this book in hand.

Further on the positive side, this book can serve as a workable introduction to American economic development, if tied to a rigorous outline of this subject and supplemented by selected material (a good start is the bibliography, pp. 193-98). The tables and charts offer a core of quantitative matter that could be put to profitable use in its own right. Similarly, Chapters 3, 6, 9, and 11 are, by themselves, valuable summaries of the state of present knowledge and research in interregional trading patterns, transport costs, and prices and incomes in the agricultural sector from 1865 through 1914. Used so as to capitalize on these stronger features, *Growth and Welfare* will provide a guide to the direction of quantitative economic history and the tools it employs, as well as to some of its accomplishments and the frontiers it has opened up.

Output, Employment, and Productivity in the United States after 1800.

National Bureau of Economic Research Studies in Income and Wealth,
Vol. 30. New York: Columbia University Press, 1966. Pp. xiv, 660.
\$12.50.

Volume 30, as this book undoubtedly will be known, joins its earlier cousin, Volume 24,¹ in the indispensable library of the U.S. economic historian. These volumes add significantly to our store of quantitative knowledge about the growth of the U.S. economy and—even more importantly—to our understanding of the nature of the data. All of the series are accompanied by detailed descriptions of their derivation, comparisons with other estimates, and suggestions as to their reliability. Historical data, as Easterlin says in a comment (p. 89), “though useful, are imperfect and mortal.” The format of the volume encourages the adoption of this realistic view.

The first third of the volume is devoted to aggregate concerns: national product estimates by Gallman revising and extending Kuznets’ data, new price deflators in fine detail by Brady, and new labor force estimates based more closely on population census data than other estimates by Lebergott. The investigators have endeavored to link their series to those available for later years, an effort that is commendable but burdened with certain costs. Gallman’s data link with Kuznets’, but the link must necessarily be imperfect since his constant price estimates are in 1860 prices while Kuznets’ are in 1929 prices. Lebergott links his series to the current series of the Bureau of Labor Statistics; they therefore differ from most earlier series which are based on the census. These difficulties are recognized and discussed by the authors.

They may not even properly be described as difficulties. In the introduction, Brady asserts that such differences give rise to opportunities for “reconciliations” of different estimates; the result being new knowledge about the

¹ *Trends in the American Economy in the Nineteenth Century*, N.B.E.R. Studies in Income and Wealth, Vol. 24, Princeton 1960.

changing interrelationships in the economy. For example, in a closely related work Lebergott found that real wages did not rise between 1850 and 1880.² In the volume at hand (p. 26), Gallman finds that real per capita income in 1874-83 was 50 per cent larger than in 1844-53. Do these estimates imply a massive redistribution of income away from labor? This would be consistent with Gallman's discovery of an important rise in the share of national product devoted to capital formation at this time (pp. 11-13), but does this picture of the economy fit with Lebergott's further finding that the share of labor in agriculture stayed constant at about 50 per cent for these years (p. 119)? Here is an unresolved problem of interest to any student of economic growth.

The next half of the volume contains papers presenting data on particular sectors of the economy. The papers on major metal mining, petroleum, and steam power are based on sources believed to have reported on the entire industry in question—although they all extrapolate from the basic data at points. The remaining papers are based on sources containing information about only part of the industries in question. With the solitary exception of McDougall's fine paper on two machine-tool firms, all of these papers use their partial information to extrapolate series for the industry as a whole.

The extrapolations, of course, are only as reliable as the assumptions used in their derivation. Davis and Stettler derive a series for total production of the cotton textile industry on the basis of a sample of firms selected on the basis of the availability of data (p. 220). A detailed comparison of the resultant series with the one derived by Robert Zevin from the state and federal census returns seems warranted as a check on the procedure.³ Eliasberg inflates various census data on coal mining on the basis of Eavenson's adjustment of the census data on output, a procedure that again assumes the sample observed to be typical of the industry.

Two other papers require assumptions of a stronger sort. Robertson derived a series for the production of metalworking machinery on the basis of data for metal-cutting machinery after 1900 and on the basis of a shifting, *ad hoc* sample before then. As Robertson makes clear, the burden of incomplete data is compounded by confusion in the definition of the industry, making the result doubly problematical. Gottlieb derived a series for the value of building in Ohio on the basis of property assessment data. As David points out in his comment, this requires strong assumptions about the nature of assessment data, assumptions which Gottlieb's references to the public spirit of Ohioans and the pressures for assessed values to conform to market values do not completely justify. Investigators must exercise considerable care in making use of these articles.

The final two essays in the volume present new data on productivity change in two important sectors of the economy and—in contrast to the bulk of the volume—go on to attempt to explain the pattern their data reveal. Parker and Klein find that mechanization was responsible for over half the increased pro-

² S. Lebergott, *Manpower in Economic Growth*, New York 1964, p. 154.

³ "The Growth of Cotton Textile Production After 1815," in Fogel and Engerman, eds., *The Reinterpretation of American Economic History* (in preparation).

ductivity in the cultivation of wheat, oats and corn in the late nineteenth century, while almost all the remainder can be accounted for by the effects of the shifting location of agriculture and the interaction of this shift with the new techniques. Fishlow finds that steel rails and heavier locomotives were important in raising railroad productivity, but that air brakes and automatic couplers were not; approximately half of the gain in productivity in railroads remains unexplained, however, when account is taken of these specific innovations. Both essays are characterized by impressive erudition and attention to alternate sources of data; it is unlikely that the correction of a few remaining defects (such as Fishlow's comparison of a chain-linked index of output with a Paasche index of inputs) would change the conclusions.

This volume, therefore, is a combination of reference work, introduction to some of the methodology of the "new" economic history, and monographic work on a few sectors of the economy. If the price for this diversity is a regrettable lack of organization, it only emphasizes the need for a new synthetic work on the economic history of our country.

PETER TEMIN

Massachusetts Institute of Technology

Development Planning. By W. ARTHUR LEWIS. New York: Harper & Row, 1966. Pp. 278. \$4.95.

Professor Lewis has written this small book on development planning "an an introduction . . . for people learning the elements of the subject, and not as a technical treatise for experts." After a short introductory chapter, in about 120 pages he discusses "Plan Strategy"; in a little less than 100, "The Arithmetic of Planning"; and in 30, "The Planning Process." There is a selective bibliography at the end of each chapter.

Under the heading of "Plan Strategy," he discusses the evaluation of projects in view of interrelationships among industries; optimum policy concerning foreign trade at successive stages of development; the problem of capital intensity; the considerations that ought to affect the regional balance of a development program; causes and remedies of unemployment during development; optimum income distribution policies; pressures on public expenditures, and appropriate principles of public expenditure, taxation, and saving policies; effects of inflation, and its control; and methods and costs of obtaining foreign aid. But this listing of topics gives little idea of the complexity of subject matter he manages to cover in brief compass. Under each topic, discussion of amazing richness is packed into between eight and eighteen pages of terse discussion.

Here and throughout the book, the discussion mixes theoretical analysis with rules of thumb derived from the author's experience. Thus: "Proposals that the amount invested should grow by more than 10 per cent per annum should normally be resisted" (since capacity of the construction industry cannot be increased faster, p. 157). And: (Except in the few countries where per capita is growing faster than 2 per cent per annum) "attempts at reducing the share of consumption by more than a half of 1 per cent per annum are likely to be frustrated by strikes, riots, inflation, or political ac-

tion" (p. 164). Lewis's least quality is mental uncertainty: he is entirely certain of his answers to the questions he poses. And, indeed, in this reviewer's judgment his answers are usually judicious. Occasionally, however, they are too pat; this is true, for example, of his explanation of the postwar flight from the countryside to the cities, and his prescription of methods to cause farmers to save.

Chapter 3, on the arithmetic of planning, outlines a procedure for arriving at a development plan. Lewis discusses successively, with arithmetical illustrations, the determinants of the rate of growth and then a method for the first approximation estimation of a feasible rate of growth, of whether the necessary financial resources will be available, and of the balance between demand and supply of commodities. (Inflation, Lewis states, is caused by excess demand for commodities. The demand for services is not directly relevant.) He then indicates how a balanced supply of the output of individual industries can be estimated by means of input-output analysis, and how the optimum allocation of production can be estimated by means of linear programming. (He discusses linear programming for pedagogical purposes, noting that the data necessary to use it will not be available.) Finally, he indicates how the relevant capital, manpower, and government budgets should be planned. All this is presented with great lucidity. It is a little disconcerting to have him note in two sentences, at the end rather than the beginning of this rather elaborate discussion, that if the "engine of growth" is import substitution, the input-output matrix is unnecessary, and if expansion of exports, irrelevant.

The final chapter presents an unexceptionable discussion of the optimum location of the planning agency and optimum planning procedures.

The description above of the contents of the book suggests its virtues, which are many. To this reviewer it seems subject to the following criticisms:

1. At least one bit of theorizing seems shaky. Lewis suggests that there are five stages of foreign trade in development (not the conventional stages of the balance of payments). He states that they are not historical states, by which he means that they do not form an inevitable succession. In the second stage, import substitution in manufacturing is exhausted. Structural inflation then occurs as the third stage, if investment in industry goes forward further without a breakthrough in agricultural production to increase the domestic supply of agricultural products. However, since by his prior reasoning there would at this point be little market for added industrial products, and since improvement in techniques alone would hardly involve an increased rate of investment, the source of the inflation-causing industrial investment is difficult to understand. The model brings the author to the conclusion, which seems remarkable to this reviewer, that Chile advanced in manufacturing early enough so that she exhausted import substitution possibilities before Brazil.

2. Except for top officials, who sometimes exhibit perverse tendencies, there are no men in the book, only cardboard cutouts. For example, though the reader is told how to plan to meet requirements for skilled, technical, and professional manpower, he is given no intimation that the success of the plan may also depend on the presence of a sufficient number of innovational entre-

preneurs. "In practice," Lewis states (p. 159), "those who invest most will also improve technology fastest," but it does not occur to him that the correlation holds only because investment is high where there is a great deal of innovational energy, and that increasing the rate of investment where the innovational drive is lacking will not yield the technical advance.

3. It is not unrelated that the author manifests little trust in the market. The logic of planning seems to have captured him as he wrote, and at times one gets the impression that without a plan no economic growth could occur anywhere. He suggests that in small countries coordination among the chief public and private decision makers can be achieved informally, but "in larger countries, like Britain or France or the United States, this argument for models is much stronger" (p. 17). One wonders whether for the moment he has forgotten reality, or whether he thinks planning *via* models would accelerate the rate of growth in Britain and the United States. As these examples illustrate, the discussion is somewhat "textbookish." A few of the recommendations seem, what Lewis notably is not, naive.

Nevertheless, there is wisdom in the book for a variety of persons interested in development planning.

EVERETT E. HAGEN

Massachusetts Institute of Technology

Economic Development and Growth. By ROBERT E. BALDWIN. New York: John Wiley & Sons, Inc., 1966. Pp. xi, 133. \$1.95.

K. A. Knopf, the editor of the Introduction to Economics Series, states that "underlying the series is the pedagogical premise that students should be introduced to economics by learning how economists think about economic problems" (p. v). Baldwin's contribution to the series serves admirably as an introduction not only to how economists think about the problems of economic development, but also to the complexities of the problems themselves.

Baldwin's presentation is organized around three general questions: "(1) What is the nature of the growth problem facing the less developed countries? (2) What are the main theories concerning the key relationships that determine a country's rate and pattern of development? (3) What are the major policy issues with which less developed countries must currently deal, and what is the best way of handling these issues?" (pp. vi-vii). The first question is discussed within the context of statistical comparisons of per capita incomes, sectoral compositions, and relative factor intensities among countries which represent widely different levels of economic development. In addition to suggesting the problems which less developed economies face, Baldwin's qualifications in respect to the comparisons provide for the beginning student valuable illustrations of the care with which a responsible economist must interpret data.

The second question is discussed within the framework of the classical, neo-classical, Marxian, Schumpeterian, and post-Keynesian theories of economic growth and the major post World War II contributions to the understanding of economic growth. The concise presentations and evaluations of the various theories are generally excellent. Some of the terminology (e.g., "liquidity

“trap,” “input-output,” “multiplier process”) and the discussion of the Harrod-Domar model, however, will require elaboration by the instructor before most beginning readers are able to understand completely the presentation.

The third question is discussed within the framework of the major policy controversies of recent years: the “Big-Push” versus the selective approach, the role of government and the role of planning, emphasis on agriculture or on manufacturing or on social overhead capital, and the problems of financing development. The discussions illustrate both the usefulness and the limitations of current development theory and of currently available empirical studies in evaluating policy alternatives.

It is virtually impossible for a text of the length of Baldwin’s to present an introduction to all the important aspects of how economists think about the problems of economic development. Shortcomings in Baldwin’s presentation include the failure to discuss explicitly the insights which historical studies of successful and unsuccessful development attempts have to offer to the less developed economies. Most instructors who assign this book undoubtedly will want to provide supplementary historical and current case studies. In most respects, however, Baldwin’s coverage is well balanced and his presentation is excellent. In the opinion of the reviewer, no other available text will better serve as an introduction to the complex problems of the less developed economies, and to how economists currently think about them.

JERE R. BEHRMAN

The University of Pennsylvania

Foreign Investment and Economic Development in China 1840-1937. By CHI-MING HOU. Cambridge: Harvard University Press, 1965. Pp. xiii, 306. \$8.95.

An important problem in forming a balanced judgment about the nature of postwar economic development in China is how to fit the Communist period into its historical context. Research in the West has concentrated so much on the former that we still do not have a clear enough picture of the state of China in the period from the end of the nineteenth century up to 1949. In viewing their own economic history, the Chinese argue that foreign political and economic domination damaged her traditional economy and retarded her overall development. Only when the Communist government finally evicted the foreigners and unified China in 1949, they argue, did modernization really begin. A basic aim of Chi-ming Hou’s book is to assess the validity of this claim.

He estimates that total foreign capital investment in China, at constant prices, rose by about 90 per cent in 1902-1914 and by 20 per cent in 1914-1931. Government borrowing abroad (which declined as a percentage, over time) was mainly used to finance the cost of civil disturbances, the heavy indemnity payments owed by China, and the construction of railways, while direct foreign investment in China was largely associated with trade. Very little went into agriculture. Hou argues that foreign capital brought several economic benefits to China and his main point here is that it played a “significant role” in creating the small modern sector which grew up between

the end of the nineteenth century and 1937. The activities of foreign enterprises stimulated the national consciousness of the Chinese and led them to take modern industrial development seriously; they created a favorable environment for profit-making, as well as providing a valuable training ground for the Chinese to acquire new skills and modern technology. Most of China's social overhead capital was financed by foreign investment. In 1933 foreign firms accounted for over 50 per cent of the total number in sawmilling, ship-building, water, gas and electricity, and during the 1930s, generally, they accounted for 40 per cent of cotton spindles and 70 per cent of looms.

Apart from being instrumental in the growth of a modern sector, Hou further argues that foreign investment did not retard or destroy Chinese economic activities. On the contrary, the Chinese share in the modern sector remained remarkably stable, despite the unequal treaties which China had to endure. In their turn the Chinese used boycotts effectively to restrict sales of foreign goods and in some cases maintained their position by dividing the market. Hou presents evidence that traditional supplies of coal, shipping, and cotton-weaving may have actually grown throughout the period, and he attributes the survival of the traditional sector to its lower costs and prices: modern (mainly foreign) firms, being capital intensive, operated with higher costs and prices than the more labor intensive, traditional enterprises and thus failed to capture the Chinese market. Finally, the author finds that, unlike the experience of some poor countries subject to foreign domination, China's trade became more diversified over time and not lopsided, mainly because so little foreign capital was invested in primary production. The deterioration in the commodity terms of trade which took place had no serious effects and could not, in any case, be blamed entirely on foreign activities.

Although it discusses under a single cover many important topics and provides an impressive amount of statistical data, this book is not a very original contribution. Professor Hou has, it is true, produced some new material relating to foreign investment but our understanding of its impact and role in the Chinese economy has been taken very little beyond the point established by C. F. Remer's researches. Similarly, in discussing various aspects of China's modernization, he has drawn extensively on the works of scholars such as A. Feuerwerker, K. C. Liu, T. C. Liu, Cheng Yu-kwei and Ou Pao-san but has added little to their findings. And while he has given weight to the point (already well established) that foreign enterprise was crucial in creating a modern sector, Hou's analysis of the effect of foreign investment on the traditional sector is too general to be acceptable. Despite the author's statement in the introduction (p. 6) that he intends to deal with the effect of foreign investment on agriculture he neglects this topic almost entirely when, in fact, it ought to have been a major subject. One of the few references to agriculture comes on page 175 when the author mentions the doubling of the cotton sown area between 1904-9 and 1929-33 but he fails to relate this to foreign investment. He does, however, devote considerable attention to handicrafts, but by treating China as a single unit ignores the crucial question: what happened to traditional economic activity in the vicinity of those few (mainly coastal) areas of China where modern industry did develop?

For the economist primarily interested in China's development, therefore, this is a disappointing and inconclusive volume and students of economic development in general will find it a trifle too specialized to be of great interest.

KENNETH R. WALKER

School of Oriental and African Studies, University of London

The Economics of Development in Small Countries—with Special Reference to the Caribbean. By WILLIAM B. DEMAS. Montreal: McGill University Press, 1965. Pp. xv, 150. \$4.50.

This book incorporates the four Callard Lectures that Mr. Demas delivered in 1964 at McGill University in connection with the recently established Centre for Developing-Area Studies. It presages a regular flow of monographs on development from the Centre. And the quality of this work augurs that the forthcoming flow could potentially represent a high capital value for the profession.

Two of the four chapters of the book refer specifically to the Caribbean—defined to include the "British Caribbean" of the Windward Islands, the Leeward Islands, Barbados and British Guiana, as well as the two independent countries of Jamaica and Trinidad and Tobago. Chapter 3 describes the characteristics of the Caribbean economies while Chapter 4 gives some meaningful insights into the process and the problems of economic planning in the area. Chapters 1 and 2, on the other hand, refer to development strategy in small countries in general—defined as the countries with a population of 10 million or less and with usable land area of 10 to 20 thousand square miles or less.

In many respects the Caribbean countries resemble their Latin American neighbors. They have high rates of population growth and high unemployment. Their resource base, apart from tourist attractions and agricultural land, includes extractive minerals—oil and natural gas in Trinidad and Tobago, bauxite in Jamaica and British Guiana. With the contribution of primary or resource exports, the economies of the Caribbean are "export trade-dominated"; the ratio of exports to GDP ranges from 25 per cent for Jamaica to just over 50 per cent for British Guiana and Trinidad and Tobago. This phenomenon—which is fairly typical of most Latin American countries—contributes to a greater degree of "external dependence" for the countries. And it has attracted both the scrutiny and strictures of the "structuralist" school of economic development (Raul Prebisch, ECLA, etc.). The rather atypical feature of the Caribbean economies, again in comparison with other Latin American countries, is monetary stability, high per capita incomes (\$1058 and \$706 for Trinidad and Tobago and for Jamaica, respectively, in 1962), and high annual rates of growth in GDP (around 8 per cent per annum in the 1950's). With the standards of the modal underdeveloped country the Caribbean economies seem to be doing rather well—and they are expected to continue doing so despite the fact that their annual rate of growth is projected to 5 per cent for the balance of the '60's due to the nonrecurrence of the rapid expansion of the mineral-exporting sectors.

On the basis of the foregoing general characteristics of the area, one could make an a priori case for applying in the Caribbean one or a combination of

several of the development strategies that are available in our professional kit of tools—the strategies of “do nothing” and “do more of the same” being distinctly among the alternatives. Instead, the author further specifies the model by emphasizing as key parameters the size of the country and the degree of “openness” of the economy; and he proposes as unique development strategy the expansion of exports of manufactures. He advocates the same strategy for all small underdeveloped countries. This reviewer, while willing to go along with the export expansion strategy in the special case of the Caribbean, fails to see why such a policy has universal validity for all small underdeveloped countries. It is the special institutional openness of the economy that recommends this strategy for the Caribbean—not the size of the country.

Small countries are likely to have highly skewed resources in comparison to the large ones. Their domestic interindustry transactions are more limited and they leave more gaps unfilled—which limits both the volume and the variety of production for the local market. Due to relatively greater specialization in a small country the domestic structure of production differs quite sharply from the domestic composition of final demand. Furthermore, economies of scale cannot be fully achieved by producing for the local market only. From this analysis the author draws two conclusions: smaller countries have greater “dependence” on foreign trade; and in the attempt to take advantage of economies of scale, export of manufactures becomes the leading sector of the economy (pp. 47-48).

Recent empirical work (e.g., Hollis Chenery, who is recognized by the author) attributes special emphasis to the role of import substitution in the process of industrialization of developing countries. It is true that small countries, because of the limited size of their market, might have to forego the benefits of economies of scale in their import-substituting industries. On the other hand, there is no reason why such industries could not become viable through tariff protection. Invisibles (e.g., tourism) is another export industry that might lend propulsion to economic development—and is immune to any effects related to the size of the country. And so is agriculture, the role of which as an “engine of growth” has been recently emphasized by many writers (e.g., T. W. Schultz, S. Kuznets, W. H. Nicholls, W. F. Owen, etc.). It appears that in most countries there is ample room for agricultural development—and this might hold especially true in the Caribbean. (Agricultural products and raw materials seem to make up from 40 to 60 per cent of the total value of imports in the Caribbean countries. And agricultural employment is 39 per cent and 21 per cent of the total in Jamaica and Trinidad and Tobago, respectively, while the sector contributes only 12 to 13 per cent of the GDP of each country.) The author does not entirely dismiss the possibility that import substitution, export of indivisibles and agriculture might play an important role in the development of smaller countries. Yet he places the main emphasis on exports of manufactures on the grounds that this industry has stronger linkage effects for transforming the whole structure of an underdeveloped economy (pp. 60, 132-33). This may or may not be so. At the present stage of the art it is difficult to identify with finality and to quantify linkage effects.

The development strategy of export creation seems, however, to be quite suitable for the specific case of the Caribbean economies that are characterized by a high degree of "openness." This openness is not so much the result of the significant share of exports in the GDP as it is the outcome of institutional factors which narrowly circumscribe the countries' financial, commercial, and monetary policies. The monetary system of the Caribbean is the characteristic colonial Currency Board system. In essence, it is a rigid form of the Gold Standard with 100 per cent backing of local currencies by sterling assets. The local currency is automatically convertible into sterling at fixed rates of exchange. No exchange controls against the sterling can be imposed. Import licensing is not widely used to protect local industry. The consequences of this dependent monetary system are that the money supply depends on the balance of payments; that deficit financing is ruled out (which explains the absence of domestic inflation); and that the rate of growth is tied to the rate of increase in exports. Under such circumstances it is only natural that there are limited possibilities of import substitution and that the export sector becomes the leading sector in the development strategy of the Caribbean countries.

In the last chapter Demas provides a brief but authoritative and insightful discussion of the rationale, the objectives, the techniques, the limitations and the problems of implementation of planning, drawn from his experience as head of the Economic Planning Division of the government of Trinidad and Tobago. As the reader may have suspected, the role of planning in small open economies like the Caribbean is rather limited. The automatic currency system guarantees that there will always be a balance in external payments. Planning then focuses on the elimination of sectoral imbalances. Yet the lack of control over the monetary and financial systems severely restricts the implementation of the plan. So does the small role played by the public sector—the share of the public sector in the total capital formation is 10 and 22 per cent for Jamaica and Trinidad and Tobago respectively. As a result, planning in the Caribbean is more indicative than it is in other underdeveloped countries. Yet it seems that even under such severe limitations a National Plan is still a valuable educative document for both business and government.

PAN A. YOTOPOULOS

University of Wisconsin—Milwaukee

Statistical Methods; Econometrics; Social Accounting

The Brookings Quarterly Econometric Model of the United States. Edited by J. S. DUESENBERY, G. FROMM, L. R. KLEIN AND E. KUH. Chicago: Rand McNally; Amsterdam: North-Holland, 1965. Pp. xiv, 776. \$9.00.

The publication of the Brookings quarterly econometric model of the post-war U.S. economy is a milestone in the development of econometric analysis.

Never before has such a large group of distinguished econometricians worked closely together and produced a coordinated research. The editors and the authors are to be congratulated on this outstanding contribution to the literature.

This project was initiated in early 1959 by the Social Science Research Council and later sponsored by the National Science Foundation. Working papers were prepared and consultation conferences held during 1961 and 1962. Beginning in September 1963, the headquarters of the project was established at the Brookings Institution. A unique feature of this project is that it will be a continuing program, which is exceedingly important. Econometrics is still a young discipline. As more and better data and new techniques of estimation become available, refinements and even basic changes in certain parts of the model may be called for. As the editors mentioned in the introduction to the volume (p. VII), the model presented "will be superseded shortly after it is published." Were it not for this reason, a review article of this monumental work, instead of the brief space allocated to this review, would be justified.

This model was constructed in the Tinbergen-Klein tradition, using simultaneous equation estimating techniques developed at the Cowles Foundation and the Netherlands School of Economics. However, the comprehensive scope, the high degree of disaggregation, and the vigor of the theoretical analysis underlying certain parts of the model (especially the investment functions) are unprecedented. All the contributors to this volume are leading experts in their respective fields, and have enriched the volume with the knowledge and experience accumulated long before the inception of this project.

A bird's-eye view of the model can be provided through a brief summary of its separate parts. J. S. Duesenberry and L. R. Klein prepared a lucid presentation of the basic research strategy. D. W. Jorgenson contributed a quite original theoretical analysis of investment anticipation and distributed lags, together with some empirical estimates on the data provided by the OBE-SEC Investment Survey. This is followed by an elaborate effort by Robert Eisner to transfer intentions into predictors of actual investment through the construction of realization equations. Eisner's work is typical of almost all the other chapters in the volume in that it is in fact a continuation and refinement of his well-known contribution in this area. Inventory equations were estimated by P. G. Darling and M. C. Lovell, much along the approach made familiar by Lovell's earlier work. Since unfilled orders played an important part in the inventory equations, an attempt was made by Manoranjan Dutta to explain the determination of new orders. S. J. Maisel's study of residential construction painstakingly began with an explanation of housing starts in terms of such unfamiliar variables as total available housing units, vacancies and net removals of these units, in addition to the often used income and demographic variables. D. B. Suits and G. R. Sparks estimated consumption functions on the stock adjustment approach, with a number of price elasticities of demand evaluated.

Previous econometric models had generally been elaborate in their treatment of the various components of effective demand, but often weak on the side of production, employment, and income distribution. This deficiency was

made up by Edwin Kuh's estimates of man-hour and employment equations both in the aggregate and for different industries and sectors, with dynamic adjustments and with production and nonproduction workers differentiated. Functions for the different components of income have also been estimated by Kuh. Another common weakness of previous econometric models is the lack of a satisfactory explanation of changes in price levels. C. L. Schultze and J. L. Tryon brought a new approach to bear on this problem by explaining price movements with markup equations at the industrial origin of production. Not since the time of the classical economists have demographic variables received as much attention as in this volume. Stanley Lebergott formulated and estimated equations which determine the labor force and marriages as endogenous variables in the model. R. R. Rhomberg and Lorette Boissonneault estimated disaggregated import and export functions and found reasonable price elasticities. In contrast to the crude manner in which the farm sector was dealt with in previous aggregate models, K. A. Fox derived functions which explained the fluctuations in farm income, prices, and inventory.

An elaborate submodel of the financial sector was developed by Frank De Leeuw, consisting of demand and supply equations, estimated on the stock adjustment approach, for seven categories of financial variables, including bank reserves, currency, demand deposits, time deposits, U.S. securities, "savings and insurance" and "private securities." An even more exhaustive system of equations was constructed by Albert Ando, E. C. Brown, and E. W. Adams to determine, as endogenous variables, most government receipts, transfers, and nondefense expenditures.

An econometric model should not be constructed merely for the satisfaction of having a self-contained system of equations. Its usefulness lies in the prospects that it will yield a satisfactory description and explanation of the historical development during the sample period, that it will serve as a forecasting scheme, and that it will contribute to intelligent policy formulation. All these require a computer program for solving a system of nonlinear difference equations. C. C. Holt developed the required program for the Brookings model and also made certain test runs.

From the point of view of econometric methodology, the chapter by F. M. Fisher on dynamic structure and estimation is the most interesting. Fisher made a compact but lucid survey of the assumptions and properties of ordinary least squares and the full information and limited information estimators. The full information method did not stand out in the comparison with as much distinction as might have been expected, not because of computational difficulties but for its relatively high sensitiveness to multicollinearity (originally pointed out by Klein and Nakamura) and specification errors. The limited information maximum likelihood estimator also suffers a higher degree of sensitiveness to multicollinearity compared with the other limited information estimators. The present popularity of the two-stage least squares method (also a member of the limited information group in dealing with simultaneous equation estimation), therefore, has some theoretical justification, unless the system is recursive, in which case the time-honored ordinary least squares method enjoys many comparative advantages. The assumptions underlying the recursive sys-

terms, however, can hardly be fulfilled in a simultaneous equation model, especially when the period of the sample observation is as long as a quarter. The use of a limited information estimator, therefore, seems unavoidable in estimating quarterly models, and the selection of proper instrumental variables becomes exceedingly important in large-size models. Fisher's contribution to the block-recursive systems and the criteria for choosing the instrumental variables greatly simplified this difficult task.

The final demand components (e.g., consumption and investment) do not coincide with the usual industrial classification of production sectors (e.g., agriculture and manufacturing). Since both schemes of disaggregation are included in the model, a bridge must be built to close the model. The output absorbed by the final demand sectors must be distributed over the production sectors, and the prices generated by the industrial markup equations must be converted to the various final demand deflators. This task was accomplished through the input-output and final-demand relationships developed by Fisher, Klein, and Yoichi Shinpai, on the groundwork done by Fox and J. Babcock.

In the final chapter, a complete model was outlined by Gary Fromm and Klein on the basis of the equations obtained for the different sectors, as summarized above, with some modification and simplification. Approximately 150 equations are genuinely estimated; others are definitions and identities. While the system is apparently not yet completely closed, the gaps do not appear to represent basic obstacles. The size of the volume already approaches 800 pages. Given the truly staggering magnitude of the work completed within a relatively short period of time, one feels more than satisfied, even though the model has not yet been applied to forecasting and policy formulation in this volume.

A rather comprehensive flow chart accompanies the volume. Before one tackles this complicated diagram, it will be helpful to study first the two illustrative equational systems developed by Fromm and Klein (this *Review*, Papers and Proceedings, May 1965, pp. 348-61) which contain the basic features of the flows and feedbacks in the complete model.

Space does not permit detailed critical comments on the various chapters separately. A few questions, however, may be raised with respect to certain broad aspects of the model.

First, perhaps the most important unsolved problem in econometric methodology is how to decide among alternative specifications. There are usually many plausible theoretical explanations of the movement of a given endogenous variable; and very often, many of them fit the sample data just about equally well. It would be ideal if it were possible to incorporate all the plausible theories into the function and let the data assign the proper weight each theory is to carry in the explanation. However, this approach has almost never worked, mostly on account of multicollinearity and the limited number of observations. The usual way out of this difficulty is to try experimental fittings on the alternative theories and then more or less arbitrarily select the result most appealing to the author concerned. Practically, all the equations presented in this volume were obtained in this manner. In a few instances, the rejected versions are presented together with the accepted ones; in the great

majority of cases, however, only those accepted are given.¹ Now that a procedure for the selection of instrumental variables has been formulated, the time has arrived to formulate a general procedure for making and rejecting specifications. The Bayes approach may or may not be a solution of this problem, but it deserves a tryout.

Second, econometric models of the Tinbergen-Klein tradition are business-cycle oriented. In a comprehensive nation-wide empirical model, it seems questionable whether it is rewarding or even legitimate to study growth and fluctuations separately. A case in point is public investment. This variable is completely absent from the model except from the point of view of government expenditure. In a sample period as long as a decade and a half, it does not appear reasonable to assume that the development of the highway systems, for instance, had no effect on production in the private sectors. The same question is relevant for all kinds of investment in social overhead, including education and public health. Public investment should at least be brought into the trend lines around which fluctuations are measured.

Practically all the equations were estimated on seasonally adjusted data. Nerlove has raised the question whether the original unadjusted data should not be used instead, so that the estimate of seasonality would become a part of model construction itself. In this way, the seasonals of the endogenous variables may be explained to an important extent by those of the exogenous variables. (See Marc Nerlove, "A Quarterly Econometric Model for the United Kingdom: A Review Article," this *Review*, March 1962, 52, 154-76.) In fact, this approach was used in the U.K. model constructed by Klein and his associates and reviewed by Nerlove in the article cited above. There are of course difficulties involved in using the seasonally unadjusted data. It would be interesting, however, to see a comparison of the results obtained by using the adjusted and the unadjusted data respectively.

The Brookings model deserves to be studied, not only by econometricians, but also by economists in general. Some of the equations developed for the various sectors of the economy may even be presented in the introductory course in economics, together with an explanation of *both the value and the limitations* of the quantitative approach. If this perhaps novel feature is added properly, the beginning course might become less remote from, and irrelevant to, the reality of economic life.

Cornell University and Brandeis University

Domestic Capital Formation in the United Kingdom 1920-1938. By C. H. FEINSTEIN. Cambridge: Cambridge University Press, 1965. Pp. xii, 270. \$17.50.

This book presents the reviewer not only with the usual problem of the trade, but also with that of two layers of authorship. The estimates were originally prepared by Mr. Maywald, and a brief summary was published by him in *The London and Cambridge Economic Bulletin* in 1960. The estimates and

¹ A mimeographed list of all tried but rejected equations would be a most valuable reference to professional econometricians.

text were then revised and the text rewritten by Mr. Feinstein. The Department of Applied Economics in Cambridge, which had initiated the project as far back as 1950, did not accept Mr. Maywald's draft. Mr. Maywald, in turn, disavows the published version. In this situation it is difficult to decide how the estimates should in the future be referred to—and referred to they will be; maybe the fairest thing would be to call them the Feinstein-Maywald estimates. Whatever the exact division of authorship, the result is undoubtedly the most thorough estimate of capital formation in the United Kingdom during the interwar period and a book that in many respects can serve in execution and presentation as a model for similar enterprises, e.g., in the "Synopsis of methods of estimation for main fixed assets."

The book consists of two chapters on concepts and methods of estimation and three chapters appraising results by comparing the new estimates with figures derived by the commodity flow method and with less complete estimates made by others (not including Maywald) and by evaluating their reliability. These are separated by a chapter briefly summarizing the results and by nine chapters describing in detail the estimates for each of the main sectors.

One of the strong points of the book is the description of sources and procedures which is done with considerably more care and in greater detail than in many publications of this type. The weaknesses of many of the estimates, unavoidable in view of the rather poor quality of the basic statistics, are frankly acknowledged. Very great ingenuity is displayed in using every available scrap of information. Some important components of the estimates, particularly those derived from corporate accounts represent new primary statistical data. It is not likely that anyone will want, or will need, to make another attempt at measuring capital formation in the United Kingdom in the 1920s and 1930s.

Interpretation of the data is another matter. Here the author limits himself to short summaries of the figures and refrains from investigating the relationship of the estimates of capital formation to other relevant economic statistics, except for the calculation of a few simple ratios, such as the average capital output ratio and the capital formation ratio. Similarly there is only a very brief discussion of problems of definitions and meaning of capital formation and stock of reproducible tangible wealth, but a clear operational description is furnished of the procedures actually adopted.

The results of this great effort are annual estimates of gross capital formation, depreciation, retirements and net capital formation and of gross and net stock of reproducible tangible assets on three price bases, namely original (first) cost, 1930 prices, and current prices. While only a few types of durable goods are distinguished—usually only structures, equipment, and inventories—the number of sectors and subsectors for which full information is given separately is large: 8 main sectors and nearly 50 subsectors of which 22 groups are within manufacturing.

The method and sources of the estimates vary greatly. The resulting estimates thus are a mosaic put together with great skill out of heterogeneous material. One main characteristic of the estimates is that greatest reliance is put

on data from the accounts of the enterprises undertaking capital expenditures rather than on figures derived by the commodity flow method, a prerequisite for the great sectoral detail in which the figures are presented. The main original contribution, and one that must have taken a very great amount of time and effort, is the compilation described in Appendix 2.1 of income accounts and balance sheets of companies listed on the London Stock Exchange (all companies with issued capital greater than £500,000 and one-third of smaller companies), which provides the basis for the estimates of capital expenditures in many subsectors, particularly in manufacturing. One would hope that this rich and otherwise inaccessible material will be made available elsewhere as fully as possible for use by other students. As usual, the figures for capital expenditures in constant prices are much more doubtful, as they had in many cases to be derived with the help of specially constructed price indices, the basis of which is often unavoidably weak.

Another characteristic of the estimates is that figures for stocks of capital are not derived by the perpetual inventory method, but start from stock estimates, usually of gross stock, for one date obtained by very different methods, which are reduced to estimates of net stock by a rather rough standard method of estimation, and are then carried forward or backward for the other years of the period on the basis of annual capital formation data.

Some of the main findings of the study, none of which is unexpected, may be summarized as follows: (1) Total capital formation in current prices averaged a little over 11 per cent of gross national product for the period 1920-38. This is by present standards a very low level, even for the United Kingdom where the ratio averaged 18 per cent in the 1950s and 13 per cent in the first decade of this century. (2) Fully one-fourth of total capital formation (1930 prices) consisted of dwellings, about 30 per cent of other structures, and an equal amount of equipment, while 8 per cent was used to increase inventories and 6 per cent to add to net foreign investment. (3) Less than about one-third of total capital formation was accounted for by industry (manufacturing, mining and power) and less than one-fifth by transportation and communication. (4) Of fixed investment, 40 per cent was public or semipublic and 60 per cent private.

From a comparison of Mr. Maywald's original estimates with the published figures it appears that the difference is not too serious for the national aggregates of capital formation. For the period as a whole Feinstein's estimates of gross fixed capital formation are 14 per cent above Maywald's on a gross, but only by 6 per cent on a net basis. Feinstein's estimates of fixed capital stock, however, are continuously and substantially below Maywald's; in 1938 e.g., by 18 per cent for the gross stock in 1930 prices. This is due primarily to the much higher estimates of Maywald for the stock of dwellings—in 1938 £7.48 billion against Feinstein's £5.47 billion, reflecting a similarly sharp difference in their benchmark estimates.

With its ample size (310 by 245 mm), large fount, beautiful typography, wide margins, good paper, and solid cloth binding, this volume, like its companions in the series, is the closest approach to a "coffee table book" (*honn*

soit qui mal y pense) that we have in the field of economics. (The first edition of the *Wealth of Nations* measures 272 by 210 mm and, of course, is printed on rag paper.) High quality is never cheap. It is therefore not astonishing that this volume sells for \$17.50 or 6.2¢ for each of its 270 pages, compared e.g., to 2 to 2½¢ for the much less sumptuous and smaller (227 by 157 mm) recent publications of the NBER. This is not meant as a criticism since the price elasticity of demand for the series probably is quite low—it will get on few individual economists' shelves, and most larger libraries will have to buy it without regard to price given the series' importance and quality.

Maxima and Minima: Theory and Economic Applications. By RAGNAR FRISCH, IN COLLABORATION WITH A. NATAF. Chicago: Rand McNally, 1966. Pp. xii, 176. \$8.50.

Economics students with limited background in mathematics are frequently puzzled—if not terrified—to find things like Lagrange multipliers, quadratic forms, and eigenvalues slipping into otherwise innocent discussions of profit maximization. Since it is not easy even yet to find a leisurely discussion of these topics which is nevertheless thorough and careful, such students should be grateful to Professor Frisch; his book goes some way toward meeting this need.

The book is an English translation of a 1960 French edition. Its 175 pages are directed largely toward determining the conditions necessary or sufficient for an extremum, possibly subject to equality constraints, of a function having continuous and bounded derivatives of any necessary order. The approach is well described by the author in his preface to the English edition:

When I have had to approach a problem requiring the use of ideas of a more advanced level than that of college mathematics, I have started with a detailed discussion of a few particularly simple special cases. But . . . I have applied to these simple cases the more elaborate method suitable for dealing with the general case. In this way, the reader is brought—in a quite intuitive manner, usually without the aid of any proof—to understand the steps leading to the generalisation. . . . Experience has shown that proceeding in this way one is able to get astonishingly far with a very moderate mathematical apparatus, and to reach an understanding of the situation which is sufficient for practical needs.

The dust jacket adds that "The book is intended first of all for economists and students of political economy without mathematical training . . .," but this has to be interpreted somewhat generously. Acquaintance with the calculus of several variables, including at least a grasp of Taylor's theorem, is a prerequisite to the book.

Chapter 1 contains a few observations on the nature of mathematical economics and on the distinction between necessary and sufficient conditions. Chapter 2 works out the maximum of a binomial expression, as an example of

extremum problems with discrete variables, and formulates a linear programming problem in standard form. Neither topic is developed further in the book. Chapter 3 discusses a few graphical examples "to show that the method of putting the derivatives equal to zero must not be applied mechanically, without circumspection" (p. 20).

The main topic is entered in Chapter 4, which employs Taylor's formula to develop necessary conditions and sufficient conditions for an extremum of a function of a single variable. (The suggestion [on p. 22] that Taylor's theorem can be fully developed merely by applying the Mean Value Theorem to successively higher derivatives seems misleadingly simple, but probably does no harm in its context.) Chapter 5 uses Taylor's expansion for several variables in the same way to obtain necessary conditions for an extremum for a function of more than one variable. The introduction of a single constraint is handled in Chapter 6 by observing that intuitively one expects that at an extreme point the normal to the constraint set should be proportional to the gradient of the function whose extremum is sought. It is then shown that this condition can be rewritten in terms of an unknown constant of proportionality whose value is determined so as to ensure satisfaction of the constraint. The case of several constraints is studied by using the constraints to eliminate some variables, and then showing that the determinantal conditions necessary for an extremum of the resulting function imply the existence of the constants which are the Lagrange multipliers. The Lagrangean function is thus a purely formal construct enabling one to write down the correct necessary conditions. A short, rather awkward "supplement" considers a direct introduction of the Lagrange multipliers, but no economic interpretation is attempted.

Chapter 7 digresses to discuss the concept of Pareto-optimality by means of an example based on an Edgeworth-Bowley box for individuals with identical utility functions $U(x,y) = xy$.

Chapters 8 and 9 deal with linear equations, homogeneous systems, and linear dependence in a thoroughly conventional way. (It is, however, surely misleading to claim that "There exist various very effective methods of calculating numerically the right hand side of (8.19) [an equation using Cramer's rule for calculating the solution of a linear system as a ratio of two determinants] even when the number of unknowns is very considerable, and may, perhaps, be counted in hundreds" (p. 68).

With this background on linear systems at hand, the text returns to the question of extrema. In Chapters 10 and 11 the dominance, in the neighborhood of a critical point, of the quadratic term of the Taylor expansion is demonstrated, and sufficient conditions based on properties of this quadratic form are developed for functions of two or several variables without constraints. The question then being to determine the properties of the quadratic form, the largest and smallest characteristic roots of the Hessian matrix are shown to provide bounds on the values assumed by the quadratic form. In Chapter 12 equality constraints are introduced, and the parallel development based on the bordered Hessian matrix is obtained by a natural extension of the preceding results. The graphical interpretation of properties of the quadratic form, and the extended discussion of the significance of the characteristic

roots of the matrix of second partial derivatives, should prove particularly helpful to students.

The book concludes with a brief account of the theory of matrices and determinants, and a three-page appendix on complex numbers. Together with Chapters 8 and 9, this material on matrices and linear systems makes up just over one-half the book.

One disadvantage of the book as a text might be well illustrated by this last chapter. Taking the position that "A matrix is simply a table of numbers arranged in rows and columns" (p. 144), the chapter proceeds to develop various relations, such as that for the determinant of a product of matrices, essentially as remarkable arithmetic facts. Though the concept of a matrix as a transformation is mentioned in an example, it is nowhere used to give intuitive substance to concepts introduced in the text. Thus the sections on matrices and linear systems tend to develop somewhat by rule, rather than by reason, even though in many cases fully adequate algebraic proofs are provided. Some insight is sacrificed by this approach.

In summary, then, the book has a highly readable account of the general features of classical extremum problems, it has a brief introduction to the elements of linear systems, and it has some illuminating examples carefully worked. As a supplementary text for the student who is taking the first course in mathematics for economists (though his heart might lie elsewhere), it should prove very appropriate. Such a student would find the material accessible, the emphasis on precise statement agreeable, the economic examples helpful, and the whole less formidable than other works (such as Harris Hancock's standard work or recent accounts such as Chapter 3 of Hadley's *Non-Linear Programming*) on the same subject. Nor would he be troubled by the fact that more general mathematical constructs, perhaps yielding more insight, are lacking in this introductory work. Most regrettable for his purposes would be the omission of any discussion of inequality constraints and the lack of any economic interpretation of Lagrange multipliers.

Though the "economic applications" are limited to a very few examples, the present book does seem still to be one of the few adequate introductions to the theory of maxima and minima accessible to the student of economics who is not skilled in mathematics.

Economic Systems; Planning and Reform; Cooperation

Modern Capitalism—The Changing Balance of Public and Private Power. By ANDREW SHONFIELD. London and New York: Oxford University Press, for the Royal Institute of International Affairs, 1965. Pp. xvi, 456. \$10.50.

Since World War II the performance of capitalism has greatly improved. Output grows more rapidly, income is better distributed, and the economy is much more stable. In part this book is an attempt to explain how this

happened and why modern capitalism has succeeded so well. Shonfield discards the idea that the improvement is of a temporary nature, or that we are simply experiencing a long upswing of a kind seen before due to special factors promoting trade and building. "The central thesis of this book is that there is no reason to suppose that the patterns of the past . . . will reassert themselves in the future."

He argues that the improvement is not due simply to the adoption of Keynesian policies of demand management. There are new institutional features of capitalism. The public authorities have vastly increased powers, and competition in the private sector has been increasingly regulated and controlled. "Governments in their anxiety to increase the area of the predictable for purposes of economic planning have encouraged firms within an industry to evolve agreed policies on the basis of their common long-range interests." Economic decision making has become coherent and the area of the unpredictable has been reduced.

The bulk of the book does not deal with the factors affecting the differential performance of various economies, or those affecting their generally improved supply potential, in the postwar period—though this is attributed largely to accelerated technological progress. Its scope is better suggested by the subtitle. It is mainly concerned with the relation between the public and the private sectors, and in analyzing whether the techniques by which modern governments manage the economy are compatible with the ideas and practice of traditional parliamentary democracy.

Most of the book is based on the assumption that economic planning is the major institutional characteristic of modern capitalism. Not all countries have accepted this in the same degree, least of all the United States, but they are all moving inexorably in this direction. At times it seems to be implied that differences in performance are due to differences in the degree to which planning has been espoused. Shonfield's prototype of modern capitalism is therefore France, where he finds plenty of evidence of planning. In other countries—such as Italy, Germany, Sweden or Austria—it requires more ingenuity to show that planning has been important.

This hypothesis can only be sustained by interpreting many different things as planning. This is done by arguing that the varying national approaches to planning derive from separate historical traditions which differ in form but not in substance—the French *étatist* tradition, Italian corporatism, and German sense of discipline, power of cartels and banks. However, the extensive historical analysis of the different approaches to "planning" emphasizes the traditional elements in policy rather than bringing out any specifically new features of modern capitalism. The argument is particularly unconvincing in the case of Germany. It is argued that coherent long-term plans for the future exist because business and banks are closely interlocked and long-term planning is done by firms themselves. It is difficult to accept that this has much in common with what happens in France, or that these features of German capitalism are new. It is also far from clear that the move towards planning is an inexorable one. In France, for instance, the opening of the economy to international trade, and the growth of a more active capital market could well reduce the existing degree of *dirigisme*.

Shonfield stresses the incoherence of the U.S. administrative tradition, which makes planning difficult, although here too he finds an "intellectual underworld of American business" who are really planners. This overemphasis on planning weakens his analysis of the reasons why the United States was so reluctant to embark on efficient Keynesian policies of demand management.

In my view Shonfield does not succeed in demonstrating that long-term planning has played as big a role in the performance of modern capitalism as he claims. Planning is something which has only recently become generally popular, and can have had little influence in the postwar growth of most countries. This is not to deny that it is an important or useful additional means to foster rapid growth. But he has mixed up his own recommendations with his analysis of what actually happened. His postulate about the decline of competition also seems exaggerated. The book largely ignores postwar developments in international trade and payments policies, and hence does not have any discussion of increased competition on this account.

In spite of its weakness as a characterization of modern capitalism, the book is excellent as an analysis of the political problems created by the large scale of government intervention in the economy. It gives a scholarly account of the administrative and parliamentary traditions in economic policy questions and a vivid picture of the working atmosphere of the economic bureaucracy in the different countries. He feels that the degree of intervention and administrative discretion which takes place in France is an inevitable feature of modern development, that this should be explicitly accepted and that civil servants in other countries should have greater liberty to express their judgments openly and be subjected to greater public scrutiny. He feels that the French type of civil service as checked by the Conseil d'Etat and Cour des Comptes is the one appropriate for our age. He also feels that government-business deals of a nonmarket character are bound to be extensive, and that the best form of parliamentary surveillance is that developed by the U.S. Congress—i.e., specialized committees to cross-examine both the executive power and business, with professional staff and public hearings.

He also expresses the need for some type of public authority which recognizes the need for active cooperation with private business, which is actively "wheeling and dealing," "seeking out allies, probing and manoeuvring for the active consensus." Here he does not prescribe any particular prototype, but one feels that the U.K. Department of Economic Affairs may be what he has in mind.

The argument on the disappearance of competition is underpinned at several key points by illustrations from defense industries. In these cases, governments must often conclude deals with a large private firm without any possibility of competition. In most European countries, there is often no means at all by which the public or the economist can make a judgment on the rationality of such government transactions. This is a field of government operations which is in urgent need of more public scrutiny and to which Shonfield's general recommendations obviously apply. However, this field of government activity raises rather special problems to which it might have been worth devoting a separate chapter.

The book is a discursive essay, which ranges over a vast array of economic and political issues. It is an illuminating and scholarly work, which does not quite live up to its ambitious and exciting title, but it provides a fascinating account of the modern balance between private and public power and of the policy issues which this raises.

ANGUS MADDISON

Paris, France

Planning in the Soviet Union. By PHILIPPE J. BERNARD. New York and London: Pergamon Press, 1966. Pp. xxv, 309. \$9.50.

This translation of a book originally published in French (Paris 1963) reports Dr. Bernard's impressions, musings, and interpretive scrabbings growing out of a two-month visit to the USSR and some scattered reading in the literature on the Soviet economy. They are pretty shallow and unrewarding. The hope that an experienced western planner like Dr. Bernard, given the opportunity to talk with a large number of responsible Soviet planners and economists, might have some solid observations and evaluations concerning Soviet planning is unfulfilled. He was struck by the differences that impress any outsider when he first contemplates the USSR and the conception of detailed centralized planning, but he offers no new information or insights. The book reeks of standard official commentary on any given problem, unilluminated by analytical guidance or by detailed factual knowledge of realities. For example, what he says about inflation is silly, i.e., that increases in bank credit to enterprises cannot lead to inflation in the consumer goods market since credit and currency move in different circuits. The discussion of the capital allocation problem as an aspect of efficiency calculations faithfully reflects the chaos of Soviet thought on the matter. As an introduction to Soviet planning, the best use to which the book could properly be put would be to implant red herrings and useless clichés in the mind of the student, against which the brilliant analysis of the instructor could then contend. Its translation and publication must indicate surplus capacity.

ROBERT W. CAMPBELL

Business Fluctuations

How Business Economists Forecast. Edited by WILLIAM F. BUTLER AND ROBERT A. KAVESH. Englewood Cliffs, N. J.: Prentice Hall, 1966. Pp. xiv, 540. \$15.95.

Applied Economic Forecasting. By HENRI THEIL, WITH G. A. C. BEERENS, C. G. DE LEEUW AND C. B. TILANUS. Chicago: Rand; Amsterdam: North-Holland, 1966. Pp. xxv, 474. \$14.00.

Although these two books both deal with the general subject of forecasting, they are distinctly different in content, technique, and overall approach. They have been written for different audiences and may accurately

represent the difference between the current frontiers of knowledge about forecasting methodology and its practice in the business and financial communities. The collection of 26 essays which were edited by W. F. Butler and R. A. Kavesh was designed to be of practical value for both economists and businessmen. The business economists were supposed to be able to improve their forecasting accuracy by applying the techniques which were contained in the collected essays, while businessmen after reading the book, were to gain insights about the manner in which the American economy functions. The primary intent of the book, however, is to demonstrate how forecasters approach the problem of predicting Gross National Product, its components, and industry and company sales. The particular emphasis is on making GNP predictions, by utilizing intuitive or judgmental techniques.

On the other hand, Henri Theil's presentation and analysis is at least one and perhaps two stages more advanced than the aforementioned approach. Theil does not attempt to outline a procedure for making forecasts, but rather presents a theoretical and empirical analysis of the accuracy of previously generated economic forecasts. This type of analysis would enable a forecaster to identify the sources of his previous errors and to undertake the necessary corrections. Theil's analysis of the predictions utilizes existing econometric and statistical techniques, but new methods for converting nonquantitative forecasts into estimates which may be judged by quantitative tools are also developed.

The macroeconomic forecasts which Theil analyzed had been generated by econometric rather than by intuitive techniques. However, it is not possible to compare the forecasting accuracy of the intuitive and econometric approaches because Theil uses European data while the collection of essays is devoted to an analysis of the American economy. In addition, the Butler and Kavesh collection does not contain an historical record of the forecasts generated by intuitive techniques which would have permitted such an analysis.

The Butler-Kavesh collection of essays is divided into five parts: (1) general approaches and techniques of forecasting, (2) procedures for forecasting GNP, (3) methods for preparing firm and industry forecasts, (4) forecasting in the financial area, and (5) the use and evaluation of forecasts. The seven chapters of Part 2 and several of the chapters of Part 3 form the core of the book. These chapters present the techniques utilized in the intuitive approach to forecasting Gross National Product and its components; however, in these chapters the difficulties associated with using this approach also become visible.

One of the difficulties of forecasting is to determine when estimates based on past relationships are no longer valid. It is, therefore, important to retain flexibility and to take fundamental changes into account when past relationships are utilized in forecasting. However, it is difficult to convert some of Butler and Kavesh's statements such as, "study inventory-sales ratios in an attempt to anticipate gluts or shortages," "further insight into capital spending may be derived from studying the reports of the National Industrial Conference Board," and "examine . . . the trend of transfers, interest,

and subsidies," into *quantitative* corrections which may be applied to estimates of inventory investment, plant and equipment expenditures, or government purchases of goods and services. Such vague procedures prevent an observer from determining whether an analyst has incorporated correct relationships into his forecasts. Moreover, evaluations of such forecasts and the development of concomitant corrective procedures cannot be undertaken. Finally, a decision maker may not know how much confidence to place in such forecasts, and it is virtually impossible for a novice to learn how to predict in this manner.

Moreover, as Butler and Kavesh indicate, after the individual components and GNP have been estimated, it is necessary to determine whether the separate estimates are consistent with each other. If not, a series of successive approximations is required to obtain consistencies which correspond to past relationships, but the authors do not want to depend upon past interrelations, for they argue that "past experience cannot be wholly relied upon," and "Judgment, consequently, must take over . . ." (p. 157). Consequently, the fundamental question is whether forecasts generated by a method in which consistency is automatically assured, even though derived from the past, might not be superior to the estimates obtained from repeated intuitive juggling. To obtain this answer, further investigations are required, for none of the authors analyze the accuracy of their respective estimates.

The chapters devoted to the individual components contain similarly vague statements stating that it is necessary to make adjustments for a variety of reasons without indicating the weight that is to be given to each factor. Nevertheless, each chapter contains some particularly useful information. M. L. Weidenbaum's description of the various government budgets can be of value to the noneconomist. Greenwald shows how the plant and equipment data and the gross private domestic investment series might be reconciled. Robinson Newcomb analyzes the demographic factors which influence long-run residential construction and indicates that the short-run movements involve deviations from the long-run trend.¹ R. J. Eggert and P. W. McCracken take the same approach in forecasting automobile consumption. They first attempt to estimate the long-run market and only then the short-run yearly deviations from this trend. They present various "rules of thumb" which might yield rough estimates of the long-run demand, but there is also some theoretical analysis which might be utilized to obtain better specifications of this demand. However, the short-run forecasting problem remains unsolved.

L. J. Paradiso's chapter on inventory investment is particularly useful. He indicates how changes in the stock of inventories are estimated and explains the difference between the changes which are derived from the book

¹ A similar but more advanced approach to forecasting residential construction was presented by S. J. Maisel, "A Theory of Fluctuations in Residential Construction Starts," *Am. Econ. Rev.*, June 1963, 53, pp. 359-83. This approach is more advanced than Newcomb's for it not only considers the factors which determine deviations from a long-run trend, but also attaches weights to each of the variables.

value of inventories and those which are obtained on a GNP basis. In addition, the relevance of inventory-sales ratios and the anticipations surveys are mentioned. Paradiso's conclusion that the anticipation data systematically understated actual inventory movements is of interest, for Theil, in his book, showed that the European survey data also yielded consistent underestimates. Since Theil has presented techniques for analyzing the predictive value of anticipatory data, an application of this technique to the U. S. data might improve the accuracy of our inventory forecasts.

R. D. Woodward presents a survey of forecasting techniques applicable to the steel industry. He indicates that an appropriate procedure to obtain steel demand would be to project the level of activity in steel-consuming industries and then to multiply these activity levels by appropriate weights. This discussion would suggest evaluating the applicability of input-output analysis for forecasting purposes, another procedure which Theil's book analyzes, but Woodward does not even consider this approach.

In other essays within the Butler-Kavesh book, F. G. Adams and P. E. de Janosi, for instance, examine the statistics and econometrics of forecasting. They note that extrapolation techniques are simple and often useful, but they do not indicate that these techniques are "naive." The discussion of econometric models would leave a layman with a false impression about their value for forecasting, for they are supposed to yield *mechanical* results. There is also no discussion about the flexibility that may be incorporated into econometric models, but a model's ability to provide consistent estimates of interrelationships is noted.

L. H. Lempert and A. T. Sommers discuss the leading series and diffusion index approaches to forecasting, but neither evaluates their record in predicting past cycles. Morris Cohen's treatment of survey data does include such *qualitative* evaluation, indicating that the data are useful as supplements to other methods and for cross checking. J. F. Rodriguez's chapter "Sources of Statistics" would be helpful to those unfamiliar with the data. It would be especially useful to economists who were attempting to reconcile figures which presented conflicting trend-cycle patterns, an occurrence which frequently confronts forecasters.

W. H. Chartener's essay on evaluating forecasts indicates the difficulty encountered in applying a standard against which historical forecasts may be judged. While mentioning naive and consensus forecasts as appropriate standards for comparisons, a statistical test, such as Theil's U coefficient which has been available since the late 1950s, is not presented. Nor does Chartener indicate that data revisions create problems in evaluating forecasts, for it is not always clear which set of figures should have been predicted.

On the other hand, Theil's book assumes that an appropriate predictive methodology exists. The book evaluates the accuracy of forecasts generated by these techniques while also advancing the frontiers of knowledge concerning forecasting techniques. This book is also divided into five parts: (1) the methodology for forecasting and evaluating predictions, (2) an analysis of past macroeconomic forecasts and estimates, (3) the application of input-

output models to forecasting, (4) the use of information theory for evaluating forecasts, and (5) an analysis of survey data.

After listing the types of predictions which may be made and discussing the functions of forecasts, Theil concludes that both the actual forecasts and the prediction procedures must be verifiable. This conclusion is at variance with the intuitive approach, for not all of the procedures of the judgmental forecasters are verifiable. If forecasting is to become less of an "art" and more of a science, it must, in this observer's view, opt for the verifiable approach. Only in this manner is it possible to examine the causes of inaccurate forecasts and undertake corrective procedures. This does not imply that all forecasts must be based upon econometric models, but if judgmental techniques are utilized, the weights and impact which are assigned to specific variables must be clearly stated. Then the accuracy of these forecasts may also be evaluated.

The value of a forecast, according to Theil, is based upon its use in making decisions. Theil shows that the loss between the decision which is made with an imperfect forecast and the decision which would have been made had the prediction been perfect is a function of the size of the prediction error. This analysis leads to the development of prediction-realization relationships in terms of predicted and actual *changes*. The prediction error can thus be measured by the inequality coefficient,

$$U = \frac{\sqrt{\sum (P_i - A_i)^2/n}}{\sqrt{\sum A_i^2/n}}.$$

The form of this particular statistic differs from Theil's previous U coefficient, for the new coefficient has no upper limit. The earlier version had an upper limit of 1, the value of the measure when no change predictions are made. Since it is conceivable that particular forecasts might be inferior to no change extrapolations, the newer statistic is a more desirable measure. (In addition, the distribution of this statistic has been derived.) This coefficient like its earlier version can be broken down to indicate whether the errors were attributable to biases or variance and covariance relationships.

In the second part of Theil's book, the inequality coefficient and other measures are applied to particular Dutch macroeconomic series, and an evaluation of the accuracy of both the forecasts and the preliminary published estimates of changes is undertaken. The preliminary estimates are examined, for these data are also subject to errors and their usefulness in interpreting economic movements is related to their accuracy. The analysis of both the estimates and the forecasts is based upon the *changes* in the series. These movements can, therefore, all be measured in logarithmic terms. Two hundred and ten observations (forecasts and estimates) on total GNP and specific individual components were available. In addition, some of the unconditional forecasts were corrected for policy changes which were induced by the forecasts.²

² The forecasts were prepared by the Central Planning Bureau of the Dutch government and thus could affect policy planning.

The characteristics of the econometric model from which the Dutch forecasts were generated include the fact that it is estimated in first differences and contains features which are particularly relevant for an open economy, but several important variables such as wages and exports were not included in early versions of the model. Theil evaluates the unconditional (*ex ante*) forecasts with the conditional (*ex post*) forecasts that would have been obtained if the predetermined (and in some cases two endogenous variables) had been predicted correctly and also develops a very important econometric technique. He shows how an equation can be added to a given model, thus replacing an exogenous variable and converting it into an endogenous one. The technique is also applicable if an endogenous variable were to be replaced with a priori information. These procedures again demonstrate the flexibility of econometric models. The actual comparison of the *ex ante* and *ex post* forecasts yields conflicting results but the former are not appreciably poorer than the latter. It is thus possible that in some cases a forecaster's judgment may modify the results generated by a model and improve their quality.

The analysis of the *ex ante* forecasts indicated that underestimates of the change accounted for 59 per cent of the observed errors. The results also showed that in the postwar period with its upward trend, a different type of error was observed when declines occurred. There were more failures to predict the declines than the advances, thus yielding more turning point errors and a smaller percentage of underestimates. The overall median inequality (U) coefficient was .56, exceeding 1.0, the value associated with no change extrapolations, for only one series. A more severe standard, based upon the error that would have resulted if each series' average yearly change had been utilized instead of the yearly predictions, was also used for evaluating the forecasts. The predictions for one-third of the series failed this stricter standard. Although Theil did not do so, it would have been interesting had the author compared the actual predictions with the forecasts generated by other standards such as the second naive model or some autoregressive structure.

Theil also notes that the pattern of economic movements is not known with precision until some time has elapsed. He, therefore, analyzes the accuracy of the earliest published estimates and determines the extent to which successive data revisions have been successful. The results show that the preliminary estimates, like the forecasts, understated the changes which occurred. In addition, only 63 per cent of the revisions were successful in reducing the absolute size of the error between the previous estimate and the change which was finally observed. Nevertheless, both the predictions and estimates improve with time and converge upon the true value.

Theil also shows how input-output tables may be used in forecasting intermediate demand, primary inputs, and sector inputs if final demand were known. Using the input-output coefficients of past tables, it is possible both to forecast the future and backcast for previous years. The older the table which is used, the larger are the errors which are observed in both the forecasts and backcasts. However, the input-output projections were superior

to extrapolations originating from final-demand-blowups when the coefficients were less than three years old. Theil also presents procedures which can be utilized to correct past tables in order to predict the future, thus providing a foundation for the methods which must be followed in order to incorporate input-output forecasts into macroeconomic predictions.

In Part IV, Theil shows how forecasts may be evaluated by that part of probability theory known as information theory. This method may be utilized whenever economic variables assume values that are all positive fractions summing to one³ i.e., the components of GNP expressed as a percentage of GNP. This approach cannot be utilized in evaluating forecasts of *changes*, which are often negative, and this procedure obviously runs counter to Theil's previously stated approach of only forecasting changes. Nevertheless, this method may be utilized to evaluate input-output and survey forecasts.

The information content of a reliable message stating that an event has occurred (i.e., the actual outcome) is related to the probability, p , with which the event was expected (i.e., forecast). The information content⁴ of a message is expressed as $\log 1/p$, and the information content of a forecast is high, i.e., accurate, "when the information obtained from the actual outcomes, given the forecasts, is small." When this method is applied to the input-output forecasts, the results indicate that the information content of the actual outcomes increases with the age of the table used. This result coincides with the previous analysis and reveals that the older the input-output table the less accurate are the forecasts.

In the final section, Theil analyzes the results of several European anticipations surveys. One of the problems involved in evaluating these surveys stems from the seminumerical form—*increase, decrease, or no change*—in which the anticipations are often expressed. In addition, it is difficult to quantify the meaning of "no change," for such a statement does not necessarily imply a zero absolute change, but rather a change within some specified small but not necessarily symmetric interval.

A retrospective analysis of German and Dutch anticipations data reveals a bias towards pessimism, which is consistent with analyses of the U. S. data. In the process of performing this evaluation, several techniques for estimating the limits of the "no change" interval were illustrated. These techniques were required to quantify the qualitative seminumerical data. On the other hand, a diffusion index type analysis of these survey data eliminates the need for quantifying no change statements, and furthermore it also has predictive value. The expected percentage change in a variable is a function of the difference between the number of survey participants who expect increases and the number who expect a decline:

$$\text{Log} \frac{X_t}{X_{t-1}} = a(X_t^1 - X_t^3),$$

³ It can be shown that the components need not sum to one, but they must still be nonnegative.

⁴ A related concept is the information inaccuracy of a forecast.

where X_t^1 and X_t^2 represent the proportion of individuals expecting increases and decreases respectively. Finally, Theil develops a method for approximating a survey realization-prediction table by a single number, which is then used to evaluate the results. Since a particular variable is often predicted inaccurately due to misestimates of some other variable, a statistical procedure for correcting the forecasts, by taking the other variables into account, is presented.

Theil has been able to develop the methodology of information theory and demonstrate its usefulness for evaluating input-output and survey forecasts. In both cases, the required statistical procedures for correcting the data may be formidable. Before this approach becomes generally acceptable, it is, therefore, likely that further methodological refinements are required. Whether information theory can be used for evaluating all economic forecasts or if its use will remain limited to specific types of predictions can only be determined in the future.

In summary, the collection of essays which Butler and Kavesh have edited has done little to lift the "aura of mystery" which has surrounded forecasting procedures. Theil, on the other hand, has demonstrated that predictions may be tied to scientific techniques. Theoretical advances in the field of forecasting will surely stem from the latter approach. Practical forecasters would clearly benefit and gain more influence if they, too, adopted this view, for they could provide more accurate predictions which would become more acceptable to decision makers. In addition, Theil's empirical results are highly relevant for the entire forecasting profession. It might, therefore, be appropriate for other economists to compare his results with forecasts of other Planning Bureaus or econometric models to determine their universality.

the Federal Reserve System*

A Trade Cycle Analysis—Extensions of the Goodwin Model. By BJORN THALBERG. Lund Economic Studies No. 2. Lund: Studentlitteratur, 1966. Pp. 126.

As the subtitle indicates, this book presents some extensions of the business cycle model suggested by Richard Goodwin in 1951. In both models, the basic features are (1) a simple consumption function in which consumption depends linearly on income, with a possible lag, (2) a flexible accelerator type of investment function with a fixed capital coefficient, (3) the production capacity limit which depends solely on the existing capital stock. Prices, labor force limitations, monetary considerations, government fiscal activities, international trade and other matters are completely abstracted from these models.

The model considered in this book is an extension of Goodwin's model in two respects. First, while in the Goodwin model, the demand for addition to capital stock is equated to investment, in this model, the demand for addition to capital takes the form of addition to backlog of orders, and the backlog of orders become investment with a fixed time-lag. Secondly, there is only one

good in Goodwin's model, while in this book there are consumption goods and one or more capital goods. The author finds it impossible to describe the characteristics of his model by analytical methods, and he reports a few simulation results of his model as an alternative. The major finding of the book is that, when these additional complications are introduced, the Goodwin model still generates what appears to be a limit cycle, but its time path is rather irregular and depends on the numerical values of the parameters.

This reviewer regrets that he cannot recommend this book to either specialists or students. A model in economic analysis is useful either because it provides an insight into some basic feature of the economy in the simplest possible context, as did the original Goodwin model, or because it presents the best possible approximation to the reality, as many recent econometric models attempt to do. Thalberg's model does not meet these requirements. The model is too complex, and the author himself has abandoned any hope of dealing with it by analytical methods. The existence of econometric models makes impossible the claim of any model like the one in this book as the useful approximation to reality.

Even under these conditions, if the book contained an exposition of some new technique for dealing with some common problems in economics, it might be rewarding reading. Unfortunately, it does not contain any such expositions.

It is hoped that future volumes of the Lund Economic Studies will be selected with somewhat higher standards.

Massachusetts Institute of Technology

Money, Credit and Banking; Monetary Policy; Consumer Finance; Mortgage Credit

Liquidity Preferences of Commercial Banks. By GEORGE R. MORRISON. Chicago: The University of Chicago Press, 1966. Pp. xi, 163. \$7.50.

Professor Morrison's monograph is a good empirical study of commercial banks' demand for cash assets and should prove to be stimulating reading for students of monetary theory. While the author's empirical tests cover the period from 1872 to 1955, the major emphasis of the monograph is on explaining the extremely large accumulation of excess reserves during the 1930s. Morrison examines several special hypotheses about the banking system during the 1930s and concludes that there is very little evidence for the widely stated view that the banking system was in a liquidity trap. Instead, he argues that the evidence supports the hypothesis that the bank's liquidity preferences shifted (i.e., the banks demanded more cash assets at any given level of interest rates) in response to the banking crisis.

Morrison develops a static, one period inventory model to describe a bank's demand for cash assets. For simplicity, the bank is assumed to be faced with a uniform distribution of cash flows. Given the random flow of cash, the bank can meet its cash requirements by holding excess cash as a buffer against ad-

verse cash flows and/or by borrowing at short term or selling earning assets. The model implies that the cash ratio varies directly with the penalty cost of meeting cash deficiencies and inversely with the expected return on earning assets and the expected cash flow.

Two special hypotheses are presented to explain the large accumulation of excess reserves following the banking crisis of 1933. They both relate to the bank's determination of the expected cash flow. The shock effect hypothesis states that "in a crisis or panic, banks immediately want to hold greatly increased amounts of cash because they have been shocked into expecting very large cash drains." There are two long adjustment lags in this model. First, the bank slowly adjusts its actual level of cash to the new higher desired level and, second, the bank slowly adjusts its expectation of a large cash outflow to correspond to the observed cash flows so that after a period of time the desired level of cash returns to a precrisis level.

The second hypothesis, and the one favored by Morrison, is the inertia effect hypothesis. In Morrison's basic model, expected cash flows are assumed to vary inversely with the difference between current and permanent deposit potential. According to the inertia effect variant of the shift hypothesis, banks revise their expectations about cash flows after a crisis by increasing the time period over which they determine their permanent deposit potential. This lengthening of the banks' horizon "tends to break the normally close link between current deposit potential and actual bank deposits" and replace it with a "more or less close link between movements of deposit potential and the excess reserve ratio." Since large inflows of reserves are expected to be only temporary, the banks hold large portions of these inflows in the form of cash. The inertia effect and the shock effect hypotheses both imply that monetary policy will be effective during periods when the banks hold large amounts of excess cash, but that it will operate with a considerable lag.

Morrison presents several pieces of evidence that contradict the idea that the banking system was in a liquidity trap during the 1930s. The most striking of these is his comparison of the Canadian and the United States banking experiences. Despite the fact that the economic environment in the two countries was very similar, both having suffered major economic depressions, the cash ratio at the Canadian banks remained approximately stable while the cash ratio at the New York banks increased rapidly. He argues that this difference in behavior can be explained by either the shock effect or the inertia effect hypothesis, since Canada did not experience any bank failures or even any significant runs on banks as the United States did. It behooves the liquidity trap supporters to explain why the cash ratio did not increase sharply in Canada as it did in the United States since fluctuations in interest rates and business activity paralleled those of the United States.

Morrison tests the two shift hypotheses by running multiple regressions on annual data from 1872 to 1914 for the New York Clearing House Banks and on monthly data from 1874 to 1913 and from 1921 to 1955 for New York banks. By including the earlier period, Morrison was able to test the hypotheses over five banking crises. The annual data show little support for the shock effect hypothesis. The call loan rate and the business failure rate are the

most important explanatory variables, but they fail to explain the magnitude of the cash ratio following the crises. The shock effect hypothesis performs better with monthly data where a more refined test can be made. It explains about one-half of the variance in the excess reserve ratio after crises. However, it performs very poorly after the 1907 crisis and also in 1933 and from 1939 to 1941. The inertia effect hypothesis explains the post crisis periods much better than the shock effect hypothesis. However, it does not do as well during normal periods. This is attributed to using a constant weight in calculating permanent deposit potential when the theory and the evidence both suggest that it should vary. Unfortunately, Morrison does not test for the statistical significance of the changes in the weight. As in the annual tests, the short term interest rate is highly significant, but it does not explain the magnitude of the cash ratio in the post crisis periods.

While Morrison's tests show that changes in the excess reserve ratio are highly correlated with changes in deposit potential following each of the banking crises, this reviewer is not convinced that this high correlation is due to a radical shift in bankers' memory spans. It seems very tenuous to base the explanation of the large accumulation of excess reserves during the end of the decade on the premise that bankers expected an outflow of reserves. After all, the three-year period from 1938 to 1940 was marked by an unprecedentedly large and continuous inflow of reserves. However, whether one agrees with the inertia effect hypotheses or not, Morrison's study is an important contribution to monetary theory. It presents a large amount of evidence and raises several interesting questions that will certainly stimulate further research about this important part of the money supply mechanism.

PETER A. FROST

Carnegie Institute of Technology

Monetary and Fiscal Policy. By HAROLD A. WOLF. Columbus, Ohio: Charles E. Merrill Books, Inc., 1966. Pp. xviii, 478. \$9.25.

One of the advantages of decentralized decision-making is faculty freedom to experiment with course content. Those who are uneasy about the usual compartmentalization of monetary and fiscal policy—the first tacked on the Money and banking, the second on to Public Finance—will welcome this intermediate text by Professor Wolf.

The first of six parts serves to introduce the distinction between money and capital markets and to identify several sources of market demands and supplies. With the exception of one short chapter on the Quantity Theory, Part 2 covers the banking side of Money and Banking: money; Federal Reserve and commercial bank organization; mechanics of bank credit creation; money, reserve, and credit supplies; and creation of member bank reserves. Part 3 takes up nonbank financial institutions. Three of the five chapters of Part 4 cover the money side of Money and Banking: types of securities and the family of interest rates; neoclassical, Keynesian, and loanable funds interest theories; and the impact of rate changes on borrowers and lenders. A fourth chapter reviews the Fed's performance over the years and a fifth summarizes the Treasury's impact on financial markets.

Part 5 covers a variety of topics related to fiscal theory and operation. There is a chapter on national income accounting and determination; one titled, "The Budget," which explores, among other things, tax shifting, burdens, and superiority of income over excise taxation; one on fiscal policy which explores the impact of government taxes and expenditures, functional finance, and Musgrave's multiple budget; one on the burden of the debt and debt management; and a summary chapter on monetary, fiscal, and debt policy coordination, its practical difficulties, and a record of Fed and Treasury cooperation.

The three chapters of the final section attempt to deepen understanding of the meaning of inflation and deflation, of the meaning of economic growth and stability, and to introduce the world of international trade and finance.

Rare indeed is the intermediate text which spans money and banking, monetary policy, fiscal policy, and debt management. One can only admire the vision which inspired such an undertaking. One can only stand in awe of the extent to which Wolf succeeds in bringing it off. Considering that an introductory text usually devotes some 300-400 pages to the same topics, this is no mean accomplishment.

To be sure, under pressure to be inclusive and yet remain within the relatively limited confines of one text, there is danger that some propositions may be gutted of their vitality or spirit. As a case in point, behind Friedman's argument for a steady-growth money supply is the notion of a more, rather than less, predictable environment. This is at once a fundamental and powerful notion. Yet on the page devoted to developing Friedman's position, "removing uncertainty" is mentioned in only one sentence (p. 389). Here and elsewhere, individual instructors will want to bring the text to life in their classroom discussions.

To those who would welcome the spanning of monetary and fiscal theory, the text as it now stands may be something of a disappointment. On the one hand, Wolf is careful to underscore the desirability of monetary-fiscal-debt policy coordination, but he does little in the way of suggesting that something deeper is involved than mere coordination. On the other hand, Wolf repeatedly faults *monetary* policy and controls as being only weakly or modestly effective when he means (or should mean) *present Federal Reserve* powers (e.g., pp. 217, 272). Taken together, there is danger that students will arrive at the end of their reading with a distorted picture of the issues involved.

One thinks of "monetary" theory as having to do with money—in particular, the quantity of money at work in an economy. For some purposes, *MV* may be an adequate expression; for others, some less aggregative formulation may be necessary. "Monetary" policy presumably refers to policy with respect to the determinants of the monetary variables. If it is clear that, say, central bank policy operates on *MV*, in a money economy it should be made equally clear that fiscal policy effects its results by operating on *MV*. The need for coordination arises precisely because fiscal actions to raise or lower *M* or *V* may be nullified by actions of the central bank—and vice versa. Both policies, properly, are subsets of the possibility set of monetary policies. At some point,

students of economic policy should come to understand that, in a fundamental sense, one does not choose between monetary and fiscal policy, but from among sets of actions by monetary and fiscal authorities.

Limiting "monetary policy" to those actions undertaken by monetary authorities should neither conceal the full range of possibilities nor the essential similarities of many alternatives. On stabilization grounds, there is little difference between the Fed directing commercial banks to increase depositor accounts by some percentage (taking care to provide the needed additional reserves) and the Treasury mailing out checks to depositors in the same amount. Similarly, there is little to choose between the Fed levying a supplementary "stabilization income tax" and the Treasury imposing higher rates to combat inflation. Blanket condemnation of monetary policy suggests that the Fed's actions would be less effective than analogous actions undertaken by the Treasury. (That neither at present has such powers in no way obviates the need for continuing clarity.)

The prolonged controversy between "monetary" and "fiscal" theorists has been sharp enough without raising another generation in its stead. To a greater extent than Wolf conveys, the controversies turn less on whether the actions of one or the other authorities more effectively promote full employment or price stability than on the implications for income distribution, for resource allocations between so-called public and private uses, for capital formation and economic growth, and on *where* authority to initiate policy should lie.

As a text, perhaps one should note also that adopters may experience some assignment problems. For students innocent beyond the introductory level, one is awed by the thought of adequately covering money and banking, monetary policy, and fiscal policy in one semester. Yet for a two-semester sequence, adequate depth and detail will require extensive supplementary reading. If students have behind them an intermediate Money and Banking course, the attention accorded the subject here is rather too extensive for review purposes. One hopes that when Wolf undertakes a revised edition, he can be persuaded to eschew the mechanics of banking in favor of a much expanded treatment of the interplay between monetary and fiscal theory and policy. If so, both colleagues and future students will owe him a debt of gratitude.

WM. CRAIG STUBBLEBINE

Claremont Men's College and Claremont Graduate School

Public Finance; Fiscal Policy

Federal Budget Projections. By GERHARD COLM AND PETER WAGNER. Washington: Brookings Institution, 1966. Pp. xx, 194. \$2.50.

Here is a book that, it is hoped, will make a difference in economic policy. Following the after-glow of the needed and wholly desirable 1964 tax reduction, we have begun uneasily to realize that a lot of problems remain in the operation of a rational and orderly fiscal policy, particularly once the narrower tolerances of a fully employed economy are regained. Indeed, prospects for the

budget have become themselves one of the major uncertainties in the economy (a fact well illustrated by events in 1966). The federal budget now embraces transactions of a magnitude equal to about 20 per cent of GNP, but we seem to stumble from one annual budget battle to the next with no real information about where the operation is going in the longer run.

We need a longer-run horizon here also if the citizenry and the Congress are to make intelligent decisions about federal programs. Should the federal government undertake a new program? Is one program more important than some other candidate? Obviously these questions cannot really be well answered in the absence of information about the rapidity and the magnitude of the budget's build-up for several years ahead. We need, in short, a longer budgetary horizon both for stabilization policy and also for the orderly operations of the public sector itself.

Can meaningful projections of the federal budget be made for several years ahead? In this study the authors endeavor to answer that question, and they have firmly established an affirmative answer. Their objective was not to provide an estimate of the budget picture for five to ten years ahead that they personally would prefer, which would be a relatively easy thing to do. Rather they have attempted to see if, through a close study of pertinent evidence, it is possible to project the future build-up of existing programs and to make some guesses about the impact of new programs during this span of years. In this effort they recognize that budget making must proceed simultaneously in two directions. It must proceed from an evaluation of individual programs to the total whose aggregate they represent. And a provisional decision must also be made about the total, the shares of which will then be allocated to the individual program claimants.

The results of Colm and Wagner's work clearly demonstrate that useful projections can be made showing where the budget is going for a period of years ahead. With this information, projections and forecasts for the whole economy could be more certain. The Congress certainly needs careful estimates of the implications for the longer run of near-term expenditure decisions. And it would be good for the Administration to lay out its longer-range strategy for the budget.

PAUL W. McCRACKEN

University of Michigan

Public Finance and Welfare—Essays in Honor of C. Ward Macy. Edited by PAUL L. KLEINSORGE. Eugene: University of Oregon Books, 1966. Pp. vii, 305. \$7.50.

Collections of essays like this one are always more attractive to the reader than to the reviewer. The latter searches for a unifying theme to agree with or dissent from, to provide a point of view for the review. But the reader is interested in the essays, or some of them, for themselves: never mind the fact that they are only loosely related.

So it is with this volume. Despite the title (and the publisher's book jacket claim), only a dozen of the 17 essays have anything to do with public finance

and, for two of them, the word finance is entirely inappropriate. Most of the essays deal with fairly topical policy problems; a few are rather more abstract. The level of discourse includes serious workman-like contributions to the professional literature, graduate-student-type essays, and journalistic pieces. There is similar unevenness evident in quality control (or rather, the lack of it) and in the strange arrangement of the essays (e.g., an essay on the property tax is presented under "National Tax Problems").

Of the essays on public finance, three are theoretical in nature. The best of these is Barry N. Siegel's essay, "On the Positive Theory of State and Local Expenditures." The literature contains valuable work on the normative theory, cast in terms of social and merits goods and wants, and also a good deal of empirical work on the determinants of state-local expenditures. Most of this lacks any hypothesizing or theoretical framework and consequently the search for variables often appears rather casual. Siegel attempts to outline a positive theory to explain expenditures. It is a bare outline, but an interesting addition to thinking in the field. The essay includes a good summary of previous empirical work, which is, if anything, too kind to the more recent imitators of the pioneering work.

George Babilot presents a useful summary of views and positions on some of the basic theoretical problems in welfare theory concerning taxation. These include: indirect versus direct taxes; the difficulty of discovering truly second-best solutions in situations in which "ideal" assumptions do not obtain and taxes are to be used as correctives; and the havoc caused by considerations of time and uncertainty. His message, stated explicitly, is that welfare theory has few answers for the policy problems of the type which must be resolved continually. Paul B. Simpson has an essay in which the tax rate schedule is treated as a democratically arrived at compromise between community desires for greater equality and for more aggregate real income. It is a showy but sterile job.

On the more topical level, the best essays include John F. Due's very good review—the only available brief review of this subject—of the form and context of value added tax proposals in the United States from the 1920s on, and Robert W. Harbeson's first-rate piece on "Some Unsettled Issues in Highway-Cost Allocation." The latter is essentially a critical review of the Bureau of Public Roads highway-cost allocation study. As Harbeson shows, the BPR study does not face up to the basic question of the scope of the commercial principle in highway finance and consequently neglects the basic conceptual issues. He is less critical, in fact, than he could be, since he places the blame on the Congressional directive for the study, not on the BPR's slavishly narrow interpretation of the directive. He calls for a study of the theoretical issues. But, as he shows, they are not really unsettled; the problem is that most people (including many economists) do not accept the obvious implications of economic analysis.

In a long essay, Lester B. McAllister, Jr., lucidly examines alternative national defense strategies (ranging from the "massive retaliation" of the late Eisenhower years to all-out disarmament) and the actual or hypothetical bud-

gets attached to each of these strategies. He argues strongly for the McNamara policies. In another long essay, Harold M. Somers reviews the arguments for and against the taxation of capital gains at death, as considered by Congress in 1963-64. His review persuaded me that the idea is a good one, but he concludes that the negative arguments prevail; in any event, he sees little hope of congressional acceptance. Robert B. Bangs reviews income tax depreciation policies, especially the reserve ratio test of the reasonableness of depreciation deductions, which went into effect in 1965; he finds the tests too inflexible.

Two essays deal with policy problems on the state-local level. Both are rambling, discursive and generally unexceptionable pieces. One is by C. Lowell Harris, on the property tax, and a second is by Howard R. Bowen, on the financing of higher education. Coverage of public finance is completed with two papers on Latin American public finance. Robert Loring Allen writes on "Regional Development and Public Finance in Venezuela." He argues from Venezuelan experience and from a simple analytical model that "unbalanced" regional growth policies are likely to be best for developing countries. That is, the greatest rate of overall growth will result from a policy of concentrating (governmental) efforts in the already most developed regions, as has been done in Venezuela. His conclusions appear eminently sensible. But one would think that Latin Americans need little inducement to do this. As Raymond F. Mikesell points out (in his essay on "Inflation and Growth") the "system" in Latin America is loaded with advantages for the "haves" and this applies to regions as well as people. Moreover, in countries with centralist traditions, the capital regions are natural favorites. The other piece on Latin America is Milton C. Taylor's essay on tax incentives in Panama, with suggestions for improving—mostly reducing—Panama's rich variety of tax incentive devices.

This is not an outstanding collection. There are relatively few pieces one would want to include in a graduate-level reading list, or read more than once. It raises once more the question of the value of books of this type; a lack-luster collection of essays cannot add to the repute of the person in whose honor they are said to be written.

International Economics

Trade, Growth, and the Balance of Payments—Essays in Honor of Gottfried Haberler. Edited by R. E. BALDWIN AND OTHERS. Chicago: Rand McNally; Amsterdam: North-Holland, 1965. Pp. viii, 267. \$8.50.

A distinguished group of economists has contributed articles in the field of international economics to commemorate the sixty-fifth birthday of one of the great figures in the field, Professor Gottfried Haberler. Problems of resource allocation and comparative advantage, the interactions between trade and development or growth, and monetary aspects of balance of payments problems all receive attention in this volume as they have in Haberler's own works.

Fourteen candles adorn the cake, and it is perhaps not surprising that some shine more brightly than others.

The two lead articles, contributed by Harry Johnson and Paul Samuelson, will probably receive the most careful attention from graduate students. In a rather lengthy but solid introductory essay Johnson discusses the welfare effects of tariffs, subsidies, and other government policies in the face of an assorted array of domestic distortions such as price rigidities (at both goods and factor levels), factor immobilities, and external economies or diseconomies in consumption and/or production. This is the land of "the second-best," and the terrain is not smooth.

Domestic distortions can either prevent the economy from being at the socially optimal point on the transformation schedule or push it below the schedule, or both. A major question concerns the effect of policies that interfere with international trade—tariffs on imports or subsidies on exports—in counteracting these distortions, especially when compared with other policies that do not discriminate between domestic and foreign consumers or producers. The point is that the optimal tariff argument emerges as the basis for any interference in trade. Domestic distortions are better corrected by other means. The essay relies on verbal and graphical arguments in illustrating the various possibilities.

Samuelson's essay, "Equalization by Trade of the Interest Rate along with the Real Wage," has been in private circulation for a few years. The question (raised by J. Bhagwati in personal correspondence) is whether the "factor price equalization" theorem implies that interest rates are equated internationally. The general answer, even with the assumptions employed in the standard Heckscher-Ohlin models is "not necessarily." The point is that by the standard theorem trade equalizes the *rentals* on capital goods (or the rents on land, or the wages of workers)—the price of capital goods needs also to be equated if the interest rate is to be equalized. In Samuelson's model this is achieved by introducing a (new) price equals cost of production equation for the capital good, with the same technology as between countries. His formal analysis includes a compact, and relatively simple, treatment of the case with any number of heterogeneous capital goods, as well as intermediate goods.

Purely theoretical essays are also contributed by Bhagwati and P. Kenen. Bhagwati examines the proposition that quotas and tariffs have equivalent effects on prices when they have the same impact in controlling imports. He argues that the equivalence depends on an assumption of competition at home and abroad and among quota holders. For example, a domestic monopoly equates marginal revenue and marginal cost, and the former will be higher with a tariff than with a quota (since *foreign* production, and through this the net demand facing the domestic monopoly, is sensitive to a price change under a tariff). Kenen presents a detailed unified treatment of the activities of an export-import firm engaged in foreign exchange speculation and forward exchange transactions. The typical firm is assumed to have a set of indifference curves relating expected net worth and (with a negative sign) risk, as expressed by his net long or short position in foreign exchange. Imports must be financed with bank credit, with interest charges rising (in either country)

with the level of borrowing. In analyzing the optimal decisions made by the firm, and the stability and comparative statics properties of the model, Kenen employs a more mathematical approach than elsewhere in this volume. This, combined with the nature of the topic, may unfortunately restrict the range of readers attracted to the essay.

The contributions of R. Caves and W. Stolper also deal with theoretical topics. Building on the work of D. Bensusan-Butt and others, Caves' essay is a beautiful literary exposition of "Vent for surplus" models of trade and growth. In contrast to the smooth neoclassical growth mechanism, these theories assert the establishment of industries (based, say, on the discovery of special natural resources or raw materials) in response to a *disequilibrium* situation, with rates of growth dictated by the speed of response (e.g., in movements of capital and/or labor) to profitable opportunities. Growth proceeds in "spurts," and those who think the real world is like this will be attracted by the model. Stolper's essay, "The Multiplier if Imports are for Investments," worries about the effect of a change in the terms of trade and challenges the standard Laursen-Metzler argument that a deterioration in the terms of trade serves to raise aggregate spending out of a given level of money income. His argument, unfortunately, is loose and not clearly stated.

The remaining essays are of a different nature. On a strictly historical level, Baldwin's essay provides an interesting discussion of the obstacles encountered by U.S. negotiators in recent tariff bargaining with the EEC. F. Machlup presents a rather taxonomic discussion of the types of action that can affect a balance of payments imbalance. Bertil Ohlin points out that the need for integrating social and economic policies as a precondition for successful free trade among a group of countries has been greatly overstated. In the opposite vein, R. Kamitz, in the most propagandistic essay of the volume, argues strongly for monetary stability as an essential prerequisite for economic integration. Whereas Kamitz would cut down the role played by government, J. Tinbergen is concerned with planning, and the value of making a distinction among international, national, regional, and local industries, based, usually, on considerations of transport cost. At a national level there need be a balance between production and demand for all categories except the first, and this leads him to consider a "semi-input-output" method. The volume concludes with three essays discussing recent monetary developments in particular countries. J. Niehans finds some interesting relationships (and a high correlation) between the import surplus and interest rates in Switzerland. And, to illustrate that international trade economists study *other* countries, C. Kindleberger reviews nine possible explanations for the persistent German surplus, while E. Sohmen concentrates on the one underlying influence affecting the U.S. balance of payments—the degree of competition in U.S. industry. Not surprisingly, he picks on steel.

There is much here to sample. In reading these contributions one can legitimately ask whether Professor Haberler has had something interesting to say about the same issues. The answer, usually, is in the affirmative.

RONALD W. JONES

University of Rochester

Synthetic Materials and the Theory of International Trade. By G. C. HUFBAUER. Cambridge: Harvard University Press, 1966. Pp. 165. \$6.50.

Kravis, in his remarkable article on "availability," pointed to the importance of trade originating not from close cost and price comparisons, *a la* Heckscher-Ohlin, but from the temporary monopolies that producers of some nations obtain by developing new products or differentiating older ones. Others, notably Hoffmeyer, Kindleberger, Burenstam-Linder, Posner, and now Hufbauer, have accompanied Kravis down this byway of trade theory with sufficient frequency that the path begins to resemble a respectable if still secondary route towards understanding recent patterns of manufactured goods trade. It has turnpike potential.

Hufbauer begins this short monograph with a terse recapitulation of three nature-of-trade theories which he wishes to test for relevancy against the experience of "footloose" industries, particularly the synthetic materials industries of plastics, synthetic rubbers, and man-made fibers. He makes short work of the factor proportions account of trade by noting that its assumptions of equal technology and constant returns to scale are inconsistent with known conditions in the synthetic materials industries. He holds open the possibility that the scale economy account, encompassing *both* static and dynamic economies, may help to explain synthetic materials trade, and properly shows that artificial trade barriers and variations in home market size, as well as significant scale economies, must exist for this to be so. But Hufbauer's principal exposition of trade theories is reserved for the technological gap account which clearly he regards as the main explanation of synthetic materials trade.

In his mind the technological gap account of trade involves far more than the temporary exports arising initially from, say, country A's industrial breakthrough. Even as country B learns how to imitate A's new development and builds its own plant, country A may reinforce its lead by harvesting static and dynamic economies, that is to say, by being first to erect an optimally sized plant and by learning-by-doing. The completion of production capacity in B, on the other hand, starts B along the learning curve and may eventually result in the replacement of B's technological gap imports with domestic output. Hufbauer's technological gap account need not end here, however, especially if wage costs are lower in B than in A. In that case country B may begin exporting "low-wage goods" to A which may be simply aging versions of the same industrial products previously exported by country A. Eventually this trade too will cease as wage disparities between countries A and B shrink or as country A develops still newer products superseding B's more traditional goods. For Hufbauer then the full technological gap account consists sequentially of technological gap trade followed by low wage trade.

This suggests, he concludes, that technological gap trade and low-wage trade usually flow in opposite directions within a trading partnership. Even so, a given country in a multicountry world may export technological goods to one set of trading partners and low-wage goods to another; the pattern depends upon the relative length of all partners' "imitation lags." Hufbauer's technological gap account therefore implies a "pecking order" of trade, populated at one end of the array with nations enjoying relatively short imitation

lags who export newer technological goods, and at the other end with poor nations whose lengthy imitation lags force them to specialize in more traditional low-wage goods.

In succeeding chapters Hufbauer tests the factor proportions, scale economies, and technological gap hypotheses for relevance to known patterns of synthetic materials trade. Yet again it is the technological gap hypothesis which receives the lion's share of his attention. From the development histories of synthetic materials like galalith, celluloid, polyethylene, and polyvinyl chloride, for example, he gleans several illustrations of trade patterns which fit nicely the expectations of his hypothesis. Another test which compares product ages with the direction of trade flows shows that for a number of advanced countries, and especially for the United States, synthetic materials exports are heavily biased towards newer products compared to those of other countries.

With yet another family of statistical tests, Hufbauer attempts to explain national shares of world synthetic materials exports with variations among countries in the aggregate imitation lag (for which each product's imitation lag is weighted by that product's share of current world exports), wage levels, the size of home markets (G. D. P.), and the accumulated volume of past production. He finds that the imitation lag helped considerably to explain export shares but that trade in only one of the product groups, man-made fibers, was responsive to the level of wage rates; this and other findings seem to suggest that low-wage trade has not been a very significant part of synthetic materials commerce. Home market size helped to explain trade shares for plastics and synthetic rubber products but not for man-made fibers, and accumulated past production proved somewhat helpful for all product groups. These four variables typically explained about ninety per cent of the variance in national export shares.

Hufbauer concludes that the technological gap theory and the scale economy theory together explain most of the trade in synthetic materials. Since some of the explanatory variables are themselves highly correlated, e.g., the imitation lag and home market size, Hufbauer's multiple regression equations, however, do not yield an approximate division between the two accounts of trade.

Anyone who has tried to understand the shifting currents of international trade over the last twenty years, and has felt the frustrations of working with elegantly polished but outdated analytic tools, should welcome and applaud this book. It brings innovations and scale economies to center stage in the theory, where they rightfully belong, and supplies the profession with the richest evidence yet of the relevance of the technological gap account to contemporary world trading patterns. The book does not reject comparative cost doctrine; rather it digs more deeply into the nature of international trade and comes up with a plausible account focusing less on static conditions external to individual industries and more on dynamic developments within each industry.

Hufbauer's technological gap account generally improves on the theory's earlier versions. In one respect, however, it regresses: it scarcely mentions the possibility of *mutual* technological gap trade being carried on *among* the richer

nations heading the trade pecking order. Yet by latest count approximately 68 per cent of world manufactured goods trade is carried on between industrial countries with increasingly similar technological skills. Is it not probable that a rising proportion, perhaps even a majority, of these nation's intragroup exports *and* imports is based on product differentiation or technological head starts? And does this not suggest that trade theorists should be as much concerned in their new quests for understanding with the sources of invention and innovation as with the processes of imitation?

Hufbauer also ignores all demand lags and measures imitation lags as the time between first commercial production in the innovating and imitating countries. Both procedures are potential sources of bias in his results. Sometimes it takes years for new goods to penetrate foreign markets, e.g., the Volkswagen in America; demand lags of this length influence the length of the trading period, making the imitation lag alone a poor measure of trading potential. My own research also suggests that a better way to measure imitation lags is to calculate some index of the rate of diffusion of an innovation within the industries of the innovating and imitating countries (*a la* Mansfield), and compare them; this requires information on more than the premier firm in each country, but it produces a much more accurate measure of national technological differences.

The book is cogent, well written, and to the point. It does not suffer as many published theses do from cumbersomeness, excessive jargon, and vast forests of charts, tables, equations, and footnotes. Most of the technical data have been pushed to the rear in orderly appendices. Apart from specialists in international trade who *must* read the book, students at the upper division as well as graduate levels would do well to study it, for the book is a model of methodological crispness and imaginative empiricism.

GORDON K. DOUGLASS

Pomona College and the Claremont Graduate School

Gold and World Power: The Dollar, the Pound, and the Plans for Reform.

By SIDNEY E. ROLFE, WITH THE ASSISTANCE OF ROBERT G. HAWKINS.
New York: Harper & Row, 1966. Pp. viii, 276. \$6.95.

Gold and World Power consists really of three short monographic essays: (1) an elementary but thoughtful and balanced elaboration of what might be called the monetary facets of international economics; (2) a critique of the various categories of proposals to alter the international adjustment mechanism or, alternatively, to augment international liquidity; and (3) a reasoned discussion of the recent strategies developed by the United Kingdom and the United States to cope with their balance of payments deficits. In each of these areas the book must be judged a success. Essential ideas and concepts are adequately covered, while peripheral and trivial issues are given proper perspective or ignored altogether. The exposition is lively and provocative. There is a felicitous blend of the theoretical, institutional, and historical approaches, with the significant consequence that abstraction is little in evidence. In many instances, rudimentary empirical evidence is imaginatively brought in to support argument and hypotheses, but it would be inaccurate to imply that the

messages of the book are adduced from quantitative materials. All this is accomplished at a level of difficulty tolerable to any conscientious undergraduate economics major and to thinking men involved in practical economic affairs. Many professional economists also will be instructed by the volume, and even specialists in international economics will find challenge and stimulation in the two chapters on U.K. and U.S. balance of payments policies.

Beyond these comments there is little to be gained by reviewing the first and second topics, or "essays," mentioned above. Professor Rolfe takes a standard position favoring improvements in the efficacy of the adjustment mechanism as a longer run target, with interim measures to enhance the liquidity of the international monetary system. Less conventionally, he seems to show a slight, although not unequivocal, preference for greater flexibility of exchange rates—even for reserve currency countries—than is currently permitted by institutional conditions and conventions. In this regard it should be noted that the author too facily glosses over the internal disruptions that may attend exchange rate flexibility. Exchange rate adjustments are a more painful remedy to balance of payments difficulties than they are here made out to be. Reallocative rigidities are not unimaginable, and some attention ought surely to be given to potential reallocative problems precipitated by exchange rate movements. Also, in his analysis of the international monetary system Rolfe persists, like nearly all economists from the North Atlantic nexus countries, in discounting the real needs and demands of the developing nations, even in the face of mounting evidence that these can no longer be realistically subordinated. I would not, however, want unduly to stress these criticisms because, on the whole and given the primer-like quality of the discussion, the two topics are competently treated.

The chapter on U.K. balance of payments tactics undoubtedly will be the most fascinating to U.S. readers. Rolfe points out that the British effort is proceeding at three levels. In the short run, the current account position is to be improved by the well-known "stop-go" aggregate demand policies. He holds reservations, however, arguing that the "stop-go" measures have been inappropriately timed since they have been tied to changes in industrial output rather than to the lagging balance of payments changes. He suggests that controlled devaluation (during periods of unused aggregate capacity) would have been more effective. In the long run, a comprehensive plan for accelerating overall productivity improvement is being implemented, although doubts remain that existing government powers are up to the task. In the intermediate-run, an incomes policy has been pursued, so as not to dissipate any gains achieved via the short-run measures. Again, Rolfe finds fault with an incomes policy, preferring rather that a controlled gap between expanding aggregate supply and demand be the instrumental variable, as has been propounded by Dow and Paish. I intend by these comments to suggest that Rolfe presents an analytical treatment of recent U.K. balance of payments policy; I recommend it highly to those not already familiar with the debate among our British colleagues.

The chapter discussing the U.S. response to its payments deficits contains less of interest, possibly because it covers more familiar ground. However, it

gives welcomed underlining to an important segment of U.S. policy that is too easily overlooked. The early differentiation in the focus of monetary policy, on the one hand, and fiscal measures on the other is, of course, mentioned. The former was redirected to induce retardation and reversal of international capital movements while the latter was designed to achieve purely domestic goals. But Rolfe stresses that these conventional measures have been augmented by reviving a host of direct controls, primarily on capital movements, that were initiated some thirty-odd years ago. These controls were, it was thought, outmoded by the world trading and payments system built up in the postwar era. Their revival in the United States is quite possibly indicative that the payments and trading system itself is dated.

M. O. CLEMENT

Dartmouth College

The Ohlin-Heckscher Theory of the Basis and Effects of Commodity Trade.

By J. L. FORD. New York: Asia Publishing House, 1965. Pp. viii, 88. \$5.75.

This brief book is a summary of the literature on the factor endowment basis for international trade, together with a discussion of the factor price equalization theorem, and a critique of Leontief's input-output evidence on the factor composition of U.S. foreign trade. Chapters 2 and 3 provide a careful restatement of Ohlin's contribution, while Chapter 4 offers a critique based mainly on the underlying assumptions. Chapter 5 is an exposé of complete factor price equalization with two factors and two commodities; while Chapter 6 is devoted entirely to Leontief's empirical findings relative to the Ohlin-Heckscher proposition that factor supplies are the principal determinant of commodity trade.

The reader who is acquainted with this literature can without loss start on Chapter 3, which discusses Ohlin's modifications to the standard assumptions basic to the theory of international specialization. These include perfect competition, constant returns to scale, qualitative uniformity of factors between countries, and fixed factor supplies. The absence of the first of these, according to Ohlin, left room for unused capacity. This meant that selling price might well be below marginal cost. In addition, the presence of political and economic instability of differing degree among trading countries, meant that prices would depart by differing percentages from marginal cost. Without pricing in proportion to marginal cost one could not say precisely how far the equalization of prices through trade would also pull factor rentals into alignment.

The presence of increasing returns when countries specialize on fewer lines of production complicates the picture further. By chance, a country might end up producing at low cost an item for which it did not have a plentiful endowment of cheap factors. Consequently trade might cause high-priced factors to become still scarcer, and move factor prices further apart, between the trading countries.

The problem of factor qualities, too, received its due from Ohlin. The now familiar point is made that higher wages can be outweighed by higher quality

of labor, so that a high-wage country may be an exporter of labor-intensive goods. A further complication is on the commodity side where the same goods may have a number of type and quality variations, such that trade in one class of goods can go in both directions at once. One can then not say clearly that relative factor supplies determine the flow of trade.

Finally, there is the influence of prices of factors on supply of labor and capital. The supply of either factor tends, in Ohlin's view, to increase with its price. The consequence of this is that trade, in making an abundant factor dearer, will also stimulate an increase in its supply. Thus unevenness of factor endowments tends to be increased by the forces of trade. While all of these points are now familiar and some have been improved on, it is interesting to remember that they were considered some thirty-five years ago by Ohlin. Ford's summary may induce some readers to reread Ohlin's book.

Chapter 4 is mainly a restatement and elaboration of the points above, together with a discussion of differences in methods of producing the same goods. Under this heading are two distinct cases. The factor-intensity reversal case emphasized by Pearce and others; and differences in technology. Here Ford points out correctly (pp. 27-29) that it is difficult to predict what the expansion of trade will do to affect factor scarcities. In the two-country, two-factor, two-good case, one can show that when country *A* produces good *X* in a labor-intensive way compared to *Y*, and *B* makes the same good in a capital-intensive way, either country may become the exporter of *X* to the other. Suppose it is *A*. If *B* is well endowed with capital and *A* is labor-plentiful, then in *A* the plentiful factor would properly be used more intensively than before. But in *B* there is also a shift to the labor-using good. Thus we can not say that trade generally makes abundant factors scarcer, since it does the opposite of this in *B*.

The author provides a useful discussion of the Leontief paradox in Chapter 6. Leontief, using an input-output matrix has calculated the labor and capital coefficients for export and for import-competing goods. The finding was that import-competing goods were capital intensive, compared to the exporting sector. The conclusion drawn was that U.S. labor efficiency is so great as to make this country in fact labor plentiful compared to the rest of the world. Ford's objections to this are: (a) productive practice abroad may be markedly different from U.S. practice, so that goods which here are capital intensive may be labor intensive abroad. This may be particularly true of some import-competing extractive industries. (b) related to (a), if we remove from the comparison those sectors where natural resources play a large role, the empirical finding is reversed, conforming to expectations that our exports ought to be capital-intensive. The conclusion drawn is that, if (b) were not there to bail us out, we still have (a) to fall back on, so that the Ohlin-Heckscher proposition is not seriously threatened.

The discussion on empirical studies relating to factor intensities would have gained in completeness by considering the work of B. S. Minhas (*Jour. Pol. Econ.*, Apr. 1962). Minhas ranked 20 comparable industries involved in international trade for the United States and Japan, as to labor-capital ratios. He found that there were numerous changes in rank ordering between the two

countries, so that the Spearman coefficient of rank correlation was rather low. Taken on its face, this would tend to weaken further the expectation that countries tend generally to export those goods which embody their plentiful factor. By the argument used earlier, one of the countries may well be pushed through trade into the "wrong" specialization.

In this reviewer's opinion, however, Minhas provided a test which was inappropriate to the question above. The breakdown of factors and commodities is to a large extent an arbitrary matter: it can be made as fine or as coarse as is appropriate to the question at hand, subject to limitations imposed by the data. For the proposition that trade between the United States and Japan tends to cause capital-intensive goods to move west and labor-intensive goods to go east, and its corollary that the two factor-price pairs move toward equality, we need only consider two industry groupings. A short-cut, using Minhas' 20 industries (see his Table V) is to see how many change position from the upper half to the lower half of his table (and vice versa). Just four out of ten switch membership from the capital-intensive to the labor-intensive camp. Consequently, if we take the 20 industries as having equal importance (in the lack of more complete information) we conclude tentatively that factor intensities in Japan are by-and-large the same for these 20 foreign-trading industries as for the United States. Contrary to Minhas' own conclusions, his data tend to support mildly the Ohlin-Heckscher proposition.

To sum up, this book, while not remarkable for originality, is a useful introduction to an important topic in the theory of international trade.

FRANZ GEHRELS

Indiana University

An Econometric Study of International Trade Flows. By H. LINNEMANN. Amsterdam: North Holland, 1966. Pp. xiv, 234. \$7.80.

Is the classical approach to econometric research in international trade correct? That is the central question left in the reader's mind after digesting the results of the very different approach used in this study.

Classically, research has been concerned with evaluating elasticities of demand and supply for exports and imports, based on data for various countries and for various commodity groups. It was hoped that such estimates would throw light on the stability of the international exchanges, to allow predictions of trends in international trade, and the like. I think it is now common ground among all students of the subject that the results of the past 30 years' work have been disappointing; and one can hardly put the blame on a shortage of numerical data. Time series on foreign trade in immense detail have been available for many decades, and in some countries even for centuries.

Without going too closely into what has so far been achieved (or not achieved!) in this field, Dr. Linnemann in this study simply decides to examine the matrix of trade flows among 80 countries in 1959; treating exports and imports separately, there are thus some 6000 flows. He tries to fit these observations into a mathematical scheme with the help of a couple of electronic computers (situated, in the way research goes these days, in Rotterdam and Cairo respectively).

To the classically trained economist, this may seem another dull cross-sectional exercise in statics and, though he would concede the possible existence of some fascinating numerical problems, he might easily be tempted—having appreciated the point of the exercise—to put down the book. He would be wrong to do so. There are indeed some tedious chapters going through three sets of laborious calculations on virtually the same model, but leading eventually to Chapter 7, on the implications of the empirical findings, which justify (at least to the reviewer's mind) the immense labor put into this project.

The basic model used throughout the analysis posits simply that the imports by *A* from *B* are greater, the greater is the national income of *A*—due to demand factors—and the greater is the national income of *B*—due to supply factors. However, as countries grow in size there is a tendency to greater self-sufficiency, and for this offsetting factor Linnemann introduces as additional explanatory variables the populations of *A* and *B*, to which the regressions in practice always attach a small negative elasticity (about -0.2). It is not very clear from the discussion why population is the correct variable for this purpose (rather than, say, national product), and whether the separate positive and negative effects of a country's size can be isolated in this way. The reader may therefore prefer to think of national-income-per-head and population size as the two equivalent variables (i.e., mathematically equivalent to national income and population size used by Linnemann) which enter into a country's demand and supply of foreign-traded goods, and as having somewhat different quantitative effects, but being positive in both cases. On the latter interpretation, Linnemann's results indicate that a rise in national-income-per-head has a greater proportional influence (elasticity about unity) on trade than does a rise in population (elasticity about 0.8).

The geographical distance between *A* and *B* is introduced into the analysis as a further variable to represent the natural resistances to trade, whether due to difficulties of commercial contact or costs of transporting the goods. In addition, dummy variables are introduced to measure the average effects of trade preference within certain trading blocs (British Commonwealth, France, etc.); and, as an afterthought, there is introduced an index measuring the degree of matching of the commodity composition of *A*'s total imports and *B*'s total exports.

Thanks to the large number of observations and their wide range of variation, the parameters of the regressions are all estimated with a fair degree of precision (as far as sampling errors are concerned). The interpretation of these estimates in terms of the underlying demand-supply structures is not gone into by the author, so little can be said as to the plausibility of their size in most cases. Nevertheless, the measure of the effects of trade preference arrangements is clear: the coefficient shows how many times trade within the bloc is greater than among countries outside the bloc that are similar in size, distance apart, etc.; the multiple is found to be surprisingly large—a factor of 8 for the British Commonwealth and 25 for the French trading bloc.

Among the topics discussed in the section on "implications," two may be mentioned here: the expected changes in trade resulting from the formation of

the Common Market; and the effect of the average distance of a country from its foreign markets on its foreign trade ratio. Whilst the analysis in neither case is definitive, it marks a distinct advance in our understanding of these complex matters.

The major limitation of the basic model is the unsatisfactory treatment of nonlinearity. A constant elasticity formulation (linear in logarithms) is adopted, but it is unsatisfactory in view of the wide range of variation; many of the trade flows among the smaller countries are zero, and the author runs into trouble from the start since he cannot incorporate these observations (minus infinity, after taking logarithms) into the analysis. Without diagrams, and there are none in this book, it is not really possible to suggest improvements; the palliatives adopted by the author (assigning arbitrary small positive values to replace the zeros, and linearizing by segments) are not found satisfactory.

The exposition is clear, precise, and unpretentious. It is a serious piece of research, and its publication will no doubt act as a healthy stimulant to further work along the new lines marked out by the author.

U.S. Production Abroad and the Balance of Payments: A Survey of Corporate Investment Experience. By JUDD POLK, IRENE W. MEISTER, AND LAWRENCE A. VEIT. New York: National Industrial Conference Board, Inc., 1966. Pp. 200. \$17.50; special prices for NICB associates, government agencies, students and teachers.

The investment behavior of U.S. manufacturing companies with operations abroad, its effect on the U.S. balance of payments, and its implications for policy are described in this NICB report. Such behavior of these companies, the authors believe, primarily concerns maintaining market positions, which typically have been established by exporting from the United States but which are inevitably eroded by foreign competition. It is much less influenced by relative rates of return. Furthermore, the costs of various types of financial capital only influence how foreign investments are financed, not whether they should be financed.

Moreover, the authors argue, since exports inevitably lose out to foreign competition, U.S. operations abroad that maintain a company's presence do not replace U.S. exports. Rather they promote U.S. exports of capital goods and intermediate products. They also create foreign interest in other U.S. products that, initially at least, are exported from the United States. Lastly they stimulate foreign economies and, hence, foreign demand for U.S. exports. All these exports would be lost, according to the authors, if investment were cut back.

But the most important result of curtailing U.S. investment abroad would be the sharp decline in earnings from abroad. Continuing earnings from manufacturing facilities "normally entail continuing investment" (p. 22). This necessity for continuing investment brings out the essential, "organic" nature of foreign operations, which reflects the need for a growing operation to maintain

earnings. The authors reject an "incremental" view of foreign investments, which relates new investments to additions to an earnings flow.

The description of corporate behavior, summarized above, was based on questionnaires and interviews with corporate executives. The results of the questionnaires were mainly useful in suggesting questions for the interview; for the authors decided very early that data from corporate accounts, which are designed to measure profits, could not be used to indicate effects of foreign operations on the U.S. balance of payments. Accordingly, in order to highlight these effects, they turned to a "qualitative" study, focusing on corporate attitudes, motives, and methods of operations. Because the qualitative approach was not supplemented with quantitative research, this study, although suggesting interesting hypotheses about corporate behavior, adds little to theoretical analysis or policy deliberations. A major conclusion, for example, that earnings will decline if the voluntary restraint program of the Commerce Department continues for a long time, is neither new nor specific enough to be helpful. How sharply and how soon earnings will decline, both critical questions, were not satisfactorily examined, although on the basis of the "organic" approach the authors presumably expected a sharp decline almost immediately.

This expectation would be realized, however, only if productive lifetimes of foreign investments are unrealistically short and unrealistically productive. Otherwise, investments could not make a profit, let alone recover their initial cost. (The question arises here whether domestic U.S. investments are as "organic" as foreign investments.) Moreover, even when using the "organic" approach to analyze earning potential, it does not necessarily follow that the current restraint program will lead to a decline in total foreign earnings. Investment on the scale of recent years can be financed by borrowings abroad and depreciation and depletion allowances, which are not covered by the program, and by capital outflows and retained earnings, which are only discouraged from rising by the program.

Other problems arise because the authors appear to have overlooked theoretical implications of what businessmen told them. For instance, the importance of maintaining market positions should have been examined critically. Specifically, the economic rationality of basing investment decisions primarily on a market-position criterion should have been explained, and it should have been made clear why prospective relative rates of return have only limited, instead of primary, bearing on investment decisions. Similarly, if "very few decisions to invest are reached by *comparing* different investment opportunities, including opportunities in the United States," the authors should not have stressed the welfare aspects of free capital movements (pp. 73, 22, 156; my emphasis).

There are additional problems. For example, by using multiplier analysis without considering the source of financing, the authors concluded that U.S. investment abroad will stimulate *both* foreign and U.S. economies at the same time. But, on the one hand, if financing is from foreign sources, the assumed purchase of equipment produced in the United States for installation abroad will be a leakage from foreign expenditure flows; whereas, on the other hand,

if financing is from U.S. sources, export of financial capital will be a leakage from U.S. expenditure flows, a leakage that is only partially offset by the equipment exports (pp. 116, 146-48). Finally, the authors referred inconsistently and inaccurately to the general intent and major details of the Commerce program (e.g., pp. 152-53).

In brief, this study of investment experience adds little to our knowledge of the balance-of-payments effects of American manufacturing investments abroad. This is due both to the failure to work through all the implications of the organic approach, including the market-position criterion, and to the absence of any quantitative verification of what businessmen said. The main benefits of the report are the numerous hypotheses for explaining business behavior that it suggests and the sample of executive thinking that it provides.

FRED B. RUCKDESCHEL

Washington, D.C.

International Trade and Finance: Theory, Policy, Practice. By FRANKLIN R. ROOT, ROLAND L. KRAMER, AND MAURICE Y. D'ARLIN. 2nd edition. Cincinnati: South-Western Publishing Co., 1966. Pp. x, 638. \$8.75.

A good textbook in international economics at the undergraduate level is hard to find these days. Perhaps more than any other course in economics at that level, with the exception of Introductory Economics, the selection of the materials for the course requires a proper blend of theory, policy, institution, and historical perspective. Students taking the course are apt to come from diverse fields of undergraduate majors, and the one centripetal force that binds them together is likely to be their common interest in current international economic issues. Ideally, therefore, a textbook in this field should make clear the logical structure of international trade theory, demonstrate its relevance to real-world problems by applying it to the analysis of major international economic issues, and provide the institutional and historical background essential for the understanding of these issues. From this viewpoint, the book being reviewed here is at once a source of felicitation and of disappointment.

Following two introductory chapters, in which some statistics on the structure of world trade and the role of the United States in that trade are laid out, the main body of the book is divided into three parts: on the theory, policy, and practice of international trade and finance, respectively.

In Part I, the theory of international trade and finance is presented in a decidedly low key. More advanced topics, such as the factor-price equalization theorem, the Leontief Paradox, the stability condition for the foreign-exchange market, the income and price effects of exchange devaluation, are all touched upon, but only lightly so as not to get involved in complex theoretical issues which at present seem to yield relatively meager tangible returns. The approach seems to be on the whole a sensible one, and its execution generally satisfactory.

Occasionally, however, the attempt to present a simple version of the theory verges dangerously on providing glib answers to what are in fact complex questions. In most of these cases, the basic problem lies perhaps not so much in the author's presentation as in the unsatisfactory state of the theory itself. On sub-

jects such as imperfect competition in international trade, and the relationship between technological progress and the structure of international trade, perhaps not much can be meaningfully said at this stage of the theory. In a few other cases, however, the answers given by the authors are oversimplified to the extent of being of dubious theoretical validity. For instance, the source of internal economies of scale is categorically attributed to the indivisibility of certain factors of production (p. 77); it is asserted that short-term capital movements are equilibrating when exchange rates are fixed, but cannot be expected to be so when exchange rates are freely fluctuating (p. 214). Such unqualified statements are either tautological, hence unhelpful, or invalid and hence misleading.

Part II on international trade and financial policies is perhaps the strongest of the three parts of the book. It starts with a brief discussion of the aims of international economic policy, then proceeds to examine various types of policy instruments for the restriction of international trade and payments. The truly commendable chapters are those dealing with topics of a historical and institutional nature. For instance, the authors' treatment of international cartels, citing case histories, makes fascinating reading of a subject students usually find dull and far removed from their concerns. The discussions of such important topics as the General Agreement on Tariffs and Trade, the International Monetary Fund, the European Economic Community, and the developments in U.S. commercial policy are the best that can be found in any of the undergraduate textbooks in international economics now on the market. A chapter on the U.S. balance of payments and international monetary reform draws material from the recent Bernstein Report on U.S. balance-of-payments statistics to elucidate the various approaches to the measurement of payments imbalance; in addition, it provides a comprehensive, up-to-date review of the policy measures adopted by the United States for correcting its persistent balance-of-payments deficits, as well as of the various proposals for the reform of the international monetary system. On all these topics, the authors have combined judicious selection of material with a lucid, lively style of writing. The results are truly gratifying.

The usefulness of this part of the book, however, is marred by an unduly narrow view of what constitutes international economic policy. The authors explain that, "for reasons of space and analytical convenience," they decided to limit international economic policy to government actions that seek *directly* to affect the conduct of international trade and payments (p. 235), thus excluding from consideration fiscal and monetary policy measures that have for many decades figured importantly in governmental programs for adjusting external imbalances. This narrow view is not only unrealistic and unhelpful, but also precludes any application of the balance-of-payments theory presented in Part I to the balance-of-payments problems and policies discussed in Part II of the book.

Part III on the practice of international trade and finance, presumably, is mainly for students with international business orientation. How this part fits in with the rest of the book is difficult to perceive. For, whereas the first two parts deal with problems of national and international resource allocation and payments adjustments, the last part is concerned solely with the operation of international business from the standpoint of individual firms. The topics

covered in Part III include such matters as the sources of information for foreign market surveys, the organization of international business firms, the incentives and obstacles to foreign business operations, and the financing of international business. As a layman to international business, this reviewer finds the treatment of these subjects exceedingly dull, and can only hope it is not typical of the materials a student has to wade through in the nation's business schools.

In conclusion, despite its many shortcomings, this book is definitely a welcome addition to the small collection of undergraduate textbooks in international economics now available on the market. In the hands of a knowledgeable and skillful instructor, Parts I and II of the book could be quite suitable for a one-semester or one-quarter course in international economics. However, in view of the misgivings stated above, it appears to fall short of the mark of a first-rate textbook. The need for a truly good undergraduate textbook in international economics remains unfilled.

Iowa State University

Business Finance; Investment and Security Markets; Insurance

A Theory of Financial Analysis. By EUGENE M. LERNER AND WILLARD T. CARLETON. New York: Harcourt, Brace & World, 1966. Pp. xii, 281. \$7.95.

The purpose of this text, in the authors' words, is "to make explicit the inter-relationships that we believe exist between Security Analysis and Corporation Finance. . . . *A Theory of Financial Analysis* is designed to provide an analytical frame of reference for the formal study of finance . . . setting forth the basic material for advanced courses in both Corporation Finance and Investments." In considerable measure, these purposes are achieved.

The student using this book should have a basic familiarity with algebra and the calculus, including the use of lagrangian multipliers. The most frequently used mathematical techniques involve optimization by means of derivatives and partial derivatives. One section in the final chapter utilizes matrix algebra; however, it may readily be omitted if desired.

Lerner and Carleton begin with two chapters on the subject of financial analysis. The first is historical, and the second introduces such concepts as the rate of return on assets and the flow of funds through the firm. The next two chapters are concerned with the capitalization of an income stream, the calculation of the internal rate of discount (time-adjusted rate of return), and the treatment of taxes. Considerable emphasis is devoted in Chapter 4 to distinguishing between accounting depreciation and economic depreciation. The authors propose this distinction as the solution to the problem of multiple rates of return.

Chapters 5 to 10 comprise the heart of the book. Fundamentally, Lerner and Carleton develop a share-price valuation model in which the several vari-

ables are subject to two constraints. The first of these constraints they call the LC function (for reasons which should be apparent). This function relates the firm's level of investment to its rate of return on assets. It reflects the conditions prevailing in the firm's product and factor markets (i.e., its demand and cost schedules). The normal assumption is made that the firm's rate of return on assets will decline as its level of investment increases. The second constraint (called the FC function) is that imposed by conditions prevailing in the financial markets. Specifically, it defines the rate of interest at which lenders will advance funds to the firm. This rate is constrained by the debt-equity ratio of the borrower. The assumption is made that the interest rate on debt available to the firm rises with its debt-equity ratio.

In Chapter 10, Lerner and Carleton proceed to develop their complete share-price valuation model and to demonstrate how share prices may be maximized subject to the two constraints mentioned above. Included are a graphic solution to the problem as well as an illustration employing specific assumed values for the parameters involved. In this chapter, the authors argue that the value of the firm is not independent of its capital structure proportions and that the position to the contrary espoused by Franco Modigliani and M. H. Miller rests upon the assumption that equity will always sell at book value.

Chapter 11 seeks to relate elements of national income economics to financial analysis. It develops equations for aggregate expenditures, an aggregate financial function, and an aggregate valuation model. The final chapter is concerned with fitting the problem of portfolio selection into the system of financial analysis developed in earlier chapters.

The book is clearly written and felicitous of style. The development of the final valuation model is logical and easy to follow, both verbally and mathematically. Each chapter is followed by a brief verbal summary of its main points and by exercises (to which answers are provided in the back of the book).

The book has substantive as well as expository strength. It provides a basic framework by means of which various factors such as the demand and cost schedules facing the firm, its level of investment, retention rate, capital structure, the interest rate on borrowable funds, and the attitudes of its shareholders toward risk may be taken into account in making the financial decisions of the firm in such a way as to maximize the price of its shares. Thus, one of the book's contributions is to integrate these several variables into a single model in such a way as to provide a logical approach to financial decision-making. At the same time, certain limitations are apparent. While the work does a good job in specifying the important variables and constraints and relating them to each other and to the valuation model, the important task of determining the appropriate values to be assigned to these variables and constraints in specific cases is, perhaps of necessity, given fairly cursory treatment. The task of putting additional meat on the model's bones remains.

This reviewer would have welcomed a fuller and more explicit treatment of the dividend decision of the firm, perhaps taking recognition of the dividend-irrelevance position and presenting the author's arguments against it, in a manner similar to that in which the capital structure problem is treated. The rela-

tionship between the capital-structure and dividend decisions might have been developed. At occasional points the assumption is implicitly made that the firm is in a condition of capital rationing. This follows from Lerner and Carleton's assumption that the firm's rate of return on assets (a measure of its level of investment) is a function of its retention rate. Under the assumption of capital rationing, the dividend decision of the firm must, of course, affect shareholders' wealth since it affects the level of investment of the firm. This assumption might have been made explicit, and, further, the implications for the model of a noncapital-rationing situation might have been explored. Also desirable would have been a more thorough treatment of the impact of uncertainty on the financial decision-making of the firm. In this connection, the assumption that investors' attitudes toward risk are fully described by the variance (or its square root) of the return is more questionable than the authors suggest.

Withal, *A Theory of Financial Analysis* is a combination of a useful textbook and a monograph that, because of its original approach to a number of problems, will interest the professional student of capital theory. As such, its appearance is welcome.

JAMES T. S. PORTERFIELD

Stanford University

The Securities Markets: Operations and Issues. By SIDNEY ROBBINS. New York: The Free Press; London: Collier-Macmillan, 1966. Pp. xvi, 303. \$7.95.

The book opens with a brief overview of the money and the capital markets and their interaction. Subsequent chapters discuss the economic basis of the securities markets, the origin and work of the Securities and Exchange Commission, the administration of the Securities Acts as an exercise in self-regulation with government and industry cooperation, criteria of efficient securities markets, the major regulatory problems that have caused controversy, and the rise of the institutional investor in the stock market with its effects. A concluding chapter on market interrelationships deals with the several trading markets for stock—both the various organized exchanges and the over-the-counter markets.

Readers will be pleased with the enlivening use of illustrations, pertinent historical material, and the selected research data. The chief research is the *Special Study of Securities Markets*, for which Robbins served as chief economist, submitted to Congress by the Securities and Exchange Commission in 1963. The recommendations in this Study led to the Securities Acts amendments of 1964 and various SEC regulations. Other studies, such as those of the Wharton group, and a variety of journal articles are also cited. This material has been organized and enriched with historical and operational background to make a most readable volume for economists, professionals in finance, and advanced students interested in the regulatory aspects of the securities markets.

Robbins stresses the need for fostering "efficient markets," defined as a pricing mechanism that "permits the maintenance of a logical relationship be-

tween a company's financial position and the price of its shares." Some of the suggestions are likely to meet with stiff criticism in business circles: a waiting period and a filing for presently unregistered secondary stock distributions (p. 90); a broader definition of "insiders" that would include anyone in possession of special material information before its public release (p. 97); extension of Federal Reserve Board control of margin requirements to collateral loans made for the purpose other than the purchase of securities (p. 105); and possibly a limitation on price swings of more than a certain magnitude (p. 150).

Probably economists will find their deepest interest in the pervasive theme that "fairer" prices can be achieved by stiffer regulation. In spite of references to Stigler, Friend, *et al.* (p. 31) and to Robinson and Bartell (p. 161), one senses a failure to distinguish between the price continuity generally accepted as desirable for the short term and the need for price to change, sometimes substantially, to reflect large changes in outlook. There also seems insufficient stress upon the difficulty, if not impossibility, of determining fair price with certainty when value depends upon future events. The past record can supply the only data that can be fed into either a computer or the mind of the expert security analyst.

Another basic question raised is how far the stock market influences the course of the economy and how far it merely mirrors expectations. The point recurs in the suggestion that institutional buying and selling is influential for the prices of particular stocks. The correlation could reflect the correct anticipation of earnings developments rather than the independent influence of institutional activity.

The fair price question rears its head again in the discussion of proper commission rates for brokerage in exchange transactions. One wonders what kind of cost data would be conclusive for fixing a fair rate schedule in a competitive personal service business such as stock brokerage. Admittedly, the business is highly cyclical and subject to over- and under-capacity even in the short run, has profits which are a mixture of capital and labor return, and provides service to small investors on what may represent a loss leader basis. How much good economics is there in the idea of basing the prices of such service upon "long-term volume expectations" (p. 187) or suggesting a flexible (compensatory) commission system that provides some assurance of a more uniform rate of return" (p. 140)?

The concluding chapter tells of the rise of certain competitive pressures for the New York Stock Exchange. The "third market" is made by a few non-member houses who offer to buy and sell certain active listed stocks as dealers, performing a function akin to that of the exchange specialist when the latter deals for his own account. The regional exchanges, notably the Midwest and Pacific exchanges, have made innovations that result in concessions from standard commissions. Such growing competition may even serve the New York Stock Exchange by reducing the threat of antitrust action.

This sampling of the book is inadequate because it centers attention on the more debatable material. It fails to give an idea of its wide scope and scholarly fairness in presenting pros and cons. Robbins does, however, take an activ-

ist's approach to regulation. If used with students, they should be acquainted with the literature of those skeptical of what securities regulation can achieve when it goes much beyond the basic areas of full disclosure and the prevention of fraud and manipulation. It is in these areas that the SEC, in cooperation with the industry, has done such an excellent job.

HARRY G. GUTHMANN

Northwestern University

The Economics of Corporate Finance. By SEYMOUR FRIEDLAND. Englewood Cliffs, N.J.: Prentice-Hall, 1966. Pp. xii, 418. \$11.95

The past five years have seen the emergence of a plethora of new books, as well as revised editions of older books, on the subject of basic business finance. The trend common to most of these books has been a shift away from the descriptive-institutional approach of the 1950s to one which incorporates analytic techniques in various degrees. Professor Friedland's objection to most of these books is the "omission of a framework for analysis on which can be hung the various analytic approaches *and* the more traditional institutional materials." His objective in this book is to develop such a framework. The framework which he selects as the central theme for the portion of the book dealing with corporate finance is "treating the firm as if it were trying to choose an optimal balance sheet." Specifically, this framework involves the selection of assets and capital sources through the application of the well-known net present value (NPV) criterion to the problem of choice among alternatives.

Part I of the book (144 pages), develops the investment decision rules for the major categories of assets—fixed assets (Ch. 2), inventory (Ch. 3), accounts receivable (Ch. 4), cash and marketable securities (Ch. 5), and the asset portfolio (Ch. 6). The approach in this part of the book can be described as an application of basic operations research techniques and some microeconomic theory to the problem of asset investment. Even though the author does not resort to direct use of calculus in the book, he does a commendable job of conveying to the reader the concepts embodied in differential calculus and probability theory and their implications for finance. Most of the subject matter is presented in a lucid and readable manner. Unfortunately, there are several areas where the quality of the results does not match the intent.

The rationale for the asserted universal applicability of the NPV criterion is developed in Chapter 2. Quite correctly the author identifies the cost of capital as the appropriate discount rate in the net present value formula and defines it as "the minimum acceptable rate of return at which the interests of the owners will not be damaged" (p. 27). I suspect, however, that despite statements such as, "Fortunately, there is a criterion of fixed asset investment which . . . provides an unambiguous and accurate means of ranking investments . . ." (p. 27), the uninitiated reader is likely to have difficulty understanding just why this criterion is so superior. The necessary tie-in between NPV and shareholder wealth is never clearly established. For example, in a subsequent chapter, the author states: "We have assumed throughout this book that the firm is trying to achieve some optimal mixture of the expected

value of net worth, which is more nearly market value than book value or any other observable valuation *and* [italics added] risk" (p. 177). Thus, the author fails to point out (or realize) that the correct use of the NPV criterion (as he himself defines it) already takes account of the element of risk. That is, the risk embodied in the returns of the firm as a whole, or in any specific project, affects the firm's cost of capital (this point is brought out very nicely by the author himself in Part II); the "value of net worth" is then merely a function of this risk-adjusted cost of capital.

In Chapter 6 the author applies an expectation/variance model to the asset portfolio decision of the firm. While his ideas are sound, his explanation is not. Again, he falls into a trap similar to the one described above. He fails to treat correctly the relationship between net expected value, expected returns, risk, and the cost of capital. Also, there are several minor but basic errors in the treatment of scrap value (pp. 34-36) and the credit selection process under uncertainty (p. 88).

Part II, which covers 98 pages, deals with the firm's capital structure decision. Following a general description of the characteristics of financial instruments and certain environmental factors in Chapters 7 and 8, the author devotes Chapter 9 to the problem of selecting an optimal capital structure. He does an excellent job of illustrating the effects of debt on the riskiness of the returns to common shareholders and discussing the dynamic nature of the capital structure decision. His conclusion, however, still evidences the confusion between expected value of net worth, expected returns, and risk . . . " . . . the firm will not necessarily attempt to achieve the highest level of expected value of net worth, but will choose a capital structure providing the most desirable mixture of return and risk available to it" (p. 194).

Chapter 10 is concerned with the determinants of the cost of capital. While certain parts of this chapter are excellent—for instance, the author's handling of the "changing capitalization rate" case (pp. 202-7)—the clarity of exposition which characterized the preceding chapters is less in evidence here. For example, the discussion of the "cost of retained earnings" (pp. 199-200) is especially ineffective. Also, throughout Part II, the author assumes what is essentially a constant expected earnings model, and fails to discuss the complications which would be introduced under other assumptions as to earnings streams. The author's conclusions on the effects of market price movements on the cost of capital are unwarranted—"Permanent changes (in market price) will increase the cost of capital when the change is downward, and lower the cost of capital when the change is upward" (p. 214). That is, he fails to consider that, even in the simple earnings capitalization model which he uses, market price is a function of *two* variables: expected earnings and the cost of capital. To attribute the cause of the change in price to only one of these variables—the cost of capital—is inappropriate. Part II concludes with two excellent appendices. The first appendix deals with the problem of leasing; the second one with mergers and business failures.

Part III is a departure from materials traditionally encountered in corporate finance texts. The six chapters in this part, covering 165 pages, provide a description in depth of the flow-of-funds social accounting system (Chs. 11

and 12), the financial sector and commercial banking (Chs. 13 and 14), non-bank financial institutions (Ch. 15), and the corporate nonfinancial sector (Ch. 16). The author justifies the inclusion of this material on the grounds that "more and more students come into the first corporate finance course with virtually no knowledge of either the money or capital markets . . ." (p. ix). This reviewer found the presentation in this part considerably less imaginative and more tedious than the material preceding it.

In summary, despite the fact that the author is often definitive where at best he should be suggestive, the book is well worth reading. Its primary contributions lie in presenting a unifying framework and in bringing together basic concepts of economics, operations research, and finance. While Part I has been subjected to considerable criticism, it is there that the author makes his most significant contributions. As a basic textbook, the book has some inadequacies: (1) there is virtually no discussion of short-term finance; (2) no problems are available in the book; (3) dividend policy is accorded a total of two pages; and (4) the discussion of the determinants of market value is perfunctory. This book's primary value as a text is likely to be in introductory finance courses within departments of economics and possibly in some intermediate level courses in business schools.

ALEXANDER A. ROBICHEK

Stanford University

Business Finance: Theory and Management. By STEPHEN H. ARCHER AND CHARLES A. D'AMBROSIO. New York: Macmillan, 1966. Pp. xvi, 556. \$8.50.

Writing a textbook in the area of business finance is not an easy task. The area is in a constant state of flux and in a perennial condition of controversy. The scope of the area ranges from the immediate appearance of the hustle and bustle of the corporate office to the longer range theoretical perspective of the ivory tower, from the inside view of one financial institution to the general outlook for a whole economy. Writing a text in this more than usually extensive and unsettled area requires a multitude of difficult decisions about the inclusion or noninclusion of topics and about the degree of finality with which to present uncertain truths. The authors have chosen not to follow blindly in the footsteps of their predecessors. They have attempted in some of the sub-areas to break their own paths, tread on new ground, and incur risks associated with new ventures.

The contents of the book, its organization, and its emphasis indicate a conscious decision on the part of Archer and D'Ambrosio to give the book a heavy dose of macroeconomic and capital-markets flavor. Of the 22 chapters in the book, Chapters 2, 3, portions of Chapter 5, Chapters 6, 7, 8 and segments of other chapters treat the macroeconomic overall view. For business (industrial) administration programs without a good required course in macroeconomics (or variations thereof: "Capital Markets," or "General Monetary Conditions," etc.) the Archer-D'Ambrosio emphasis on the general view is an extremely useful addition to a business finance course.

The emphasis of Chapter 5 is new for a business finance book. Written in

collaboration with W. F. Sharpe, it explores with the help of indifference curves the process of choice between investments of differing risks and of differing expected rates of return. It sets an economics-theoretical tone for subsequent discussions of risk. There is little doubt that potential users will find this chapter an especially beneficial and helpful feature of the book.

The book highlights and emphasizes risk. Interest rates (rates of return) are not only differentiated by their levels but also by the risks accompanying these levels. The student is constantly made cognizant of the need to take into account, simultaneously, both the yield and risk dimensions of investments. The emphasis on risk is a useful one. It repeatedly communicates the inadvisability of abstraction from the risk dimension and constantly conveys the basic notion that risk is a part and parcel of the "commodity" called investment.

Some omissions in the book are regrettable. Notably absent are a discussion of risk preference, an acknowledgement of limitations of profit definitions including the one favored by the authors, and the evaluation of difficulties inherent in the empirical estimation of rates of return. (1) The attribution of risk aversion to all segments of the capital market and to all managerial capital budgeters, no more than a convenient assumption at the outset, remains to influence the entire book. It is never seriously questioned or critically evaluated. Risk preference, not at all unlikely to be the dominant characteristic of some segments of the market, remains an important unexplored possibility. (2) The discussion of findings relating to random walks of stock prices could have been included advantageously either at the cost of an addition to the book or at the expense of another topic. One of the major results of the investigation of the random walk of a stock price is the lack of correlation between consecutive changes in stock prices (ownership values). This result suggests that a profit definition which relies heavily on changes in the value of ownership, as does the profit definition the authors favor, may not be useful for the formation of expectations about future profits. (3) The effect of lack of information and of errors of measurement on the actual empirical evaluation of rates of return on equity and assets as well as on estimates of future yields on investment projects have not been sufficiently treated.

An emphasis on the total macroeconomic picture and a heavy concentration on the implications of risk for investment behavior constitute the bulk of the first part of the book, Chapters 1-8, and a framework within which the rest of the book is written and developed. The second part of the book, Chapters 9-13, is what might be most aptly described as an economic theoretical descriptive discussion of profits and the factors affecting the demand for and supply of capital (loanable funds) as viewed and experienced by an individual firm and by its suppliers of capital. The third part, Chapters 14-22, treats topics which are customarily included in a text on business finance: management of the investment and capital budgeting processes, financing and refinancing decisions, and ratio analysis. Problems at the end of chapters, designed to help the student acquire a concrete understanding of the conceptual material in the text, are a useful pedagogical addition.

Despite the omissions mentioned earlier the text is a satisfactory teaching

instrument. It will be especially welcomed by instructors who choose to use their own supplementary materials for some of the details of financial management and for topics of special interest and who prefer an emphasis on general market forces.

HASKEL BENISHAY

Washington University, St. Louis

Business Organization; Managerial Economics; Marketing; Accounting

Accounting, Evaluation and Economic Behavior. By RAYMOND J. CHAMBERS. Englewood Cliffs: Prentice-Hall, 1966. Pp. xii, 388. \$7.50.

There are few basic works in the literature of accounting that undertake a thoroughly theoretical approach. Indeed, most writing by accountants or about accounting is concerned with applications of existing rules of practice to specific situations, the tracing of precedents for or against some procedure, or with teaching the methods and techniques currently used by professional accountants. Scattered throughout the articles and textbooks, one finds protests by a few academicians and practitioners against the inconsistent body of rules that are known as "generally accepted principles of accounting." These protests have sometimes contrasted accounting with economics in order to develop a structured system of accounting definitions and rules (e.g., J. G. Canning, *The Economics of Accounting*, 1929); have been concerned about the effects of price level changes and called for and described a system of constant dollar accounting (e.g., H. W. Sweeney, *Stabilized Accounting*, 1936); have presented a plea for meaningful accounting reports (e.g., K. MacNeal, *Truth in Accounting*, 1939); have presented a system of accounting based on "practical" considerations, such as cost-based measurements that can be readily audited (e.g., W. A. Paton and A. C. Littleton, *An Introduction to Corporate Accounting Standards*, 1940); and have sought to develop and describe a system in which trading income and capital (or holding) gains are reported separately (e.g., E. O. Edwards and P. W. Bell, *The Theory and Measurement of Business Income*, 1961). Professor Chambers' book is one of the most recent of this genre.

On the jacket Chambers' book is described as "A thorough and literate foundation for a system of accounting, developing the many facets of the function of accounting as an aid to the efficient management and development of the economic institutions of an industrial society." This foundation is built of propositions that are ". . . admitted only because their premises are believed to be acceptable or demonstrable and because they comprise a consistent system" (p. 10). The propositions are drawn from the theory of signs and language, measurements, logic, social structures, communication, etc. The belief in their acceptability is based on copious references to authorities in these fields. (The economist quoted most often is von Mises.)

The system of argument is predominantly deductive. Statements about

human behavior, perception, needs, institutions, etc. are made and supported by many references to the assertions and conclusions of authoritative writers in many fields. Each chapter is followed by an outline, in flow-chart form, and a list of numbered definitions and assumptions, from which inferences and conclusions are drawn and also numbered. After each conclusion, one or more numbers are given that refer back to a previously drawn conclusion or assumption on which it is based or related in some way. The net result of this form of argument is a carefully built up, apparently logically consistent system, upon which a theory of accounting is to rest. (I use the word "apparently" because, despite the heroic efforts of the author to provide schematics and cross-referenced statements, I find it extremely difficult to keep track of the basis for the multitude of assertive statements made. Perhaps a reason for my problem is that Chambers uses philosophical terminology that prevented my fully understanding the points being made.)

The first three chapters (about a fifth of the book) construct, from basic assumptions, the milieu in which an accounting system functions. Chambers begins with statements and definitions about the behavior of people: their capacity for perception, motivation for action, reaction to stimuli, and capacity for and method of reasoning, learning and belief. His following discussion on the achievement of desired ends is based on these statements. "Actors" are said to choose among alternative means to the desired ends by discovery and evaluation of the consequences and marginal utilities of their actions. The "environment of action"—natural and social, legal, and economic—is considered next. The conclusion drawn from these introductory chapters is that an entity must be able to choose among alternative causes of action and adapt to changing conditions in order to survive.

Chapter 4, "Monetary Calculation," contains Chamber's conclusions about the function and method of accounting. He argues that the ability of an entity to adapt by engaging in market exchanges is measured by ". . . the simple financial property which is uniformly relevant at a point of time for all possible future actions in markets . . . the market selling price or realizable price of any or all goods held" (p. 92). "We therefore define accounting functionally, as a method of retrospective and contemporary monetary calculation the purpose of which is to provide a continuous source of financial information as a guide to future action in markets" (p. 99).

The remaining two-thirds of the book presents useful elaborations of the conclusion—an illustration of the effects of not making price level adjustments, a discussion of the application of current market prices to different types of assets, a consideration of accounting for trading ventures, corporations, and nonprofit organizations, as well as additional statements about behavioral problems and some basic and often irrelevant observations about such subjects as double entry bookkeeping and epistemology.

Chamber's key conclusion, that assets should be measured at contemporary market prices and income measured as the change in these asset amounts (adjusted for changes in general price levels and investments in the entity), differs from the present value approach favored by most economists. He rejects present value because the calculations are not based on current market

"facts," but rather on expectations about the future. Considering that Chambers believes that financial statements should show the short-term ability of the entity to adjust by selling or buying individual assets, his rejection of present values may be justified. However, his valuation rule requires that the assets of an entity always be stated at the lower of exchange or use values. It is difficult, for me at least, to conclude (even granting Chambers' premises) that this is or might be the sole function of accounting data. To give just one example, consider that the cost of a specialized machine would be shown as an expense in the period of its purchase, if it has no resale value (net of transaction costs), even though it has high use value. If managers and/or owners view the accounting statements seriously, what might the effect of this procedure be on their decisions to acquire assets?

A different type of problem that one encounters with this book, perhaps because of the theoretical approach that Chambers takes, is that he does not consider adequately the practical problems of measuring asset values in terms of current market prices. Chambers asserts that "... whether or not [a person] chooses to discover his financial position, that position is discoverable" (p. 81), in terms of the current cash equivalent of his assets. But the amounts that may be received for assets differ when they are sold singly or in groups, even when unambiguous market prices exist for specific assets. (This fact violates the principle of additivity about which Chambers is very concerned). Nor is the market price of manufactured goods known until they are sold. (Interestingly, in the brief paragraph or two in which he considers the problem of manufactured goods, Chambers seems to suggest that traditional cost allocations be made, with the exception that original costs be restated at current market prices.) Indeed, the essential problem for accountants, in my opinion, is that of measurement. I believe that it behooves the proponent of a theory of accounting to spell out, in detail, how his concepts can be made operational.

It would seem, given the as yet unsolved problems of valuing assets, either in terms of current market price, present value or in some other way, that Chambers would favor accounting statements in which assets are valued on several bases. But he rejects this notion emphatically, on the grounds that only one method can be correct.

At the conclusion of his book, Chambers likens his work to that of Copernicus; he envisions a similar Copernican revolution in accounting thought. As he notes, others have complained about the inconsistencies and meaninglessness of much accounting practice. Considering the pragmatic orientation of accountants, it is doubtful if Chambers' formal axiomatic presentation, with its limited consideration of methods of measurement and recording, will be as effective as he hopes. Nevertheless, Chambers has provided us with a rigorously constructed system that attempts to integrate accounting theory with other disciplines. In so doing, he has prepared a strong foundation upon which additional research into the measurement and reporting techniques of accounting can proceed.

GEORGE J. BENSTON

University of Rochester

Industrial Organization; Government and Business; Industry Studies

International Differences in Industrial Structure. By JOE S. BAIN. New Haven and London: Yale University Press, 1966. Pp. xv, 209. \$5.00; paper, \$1.45.

Professor Bain's contributions to the study of industrial structure and performance are well known and highly regarded. His latest monograph, which has the great merit of brevity, compares certain aspects of the structure of a number of manufacturing industries in eight countries: the United States, Britain, Canada, France, Italy, Sweden, India, and Japan. The quantitative comparisons deal with plant size, plant concentration, firm concentration, and the relation between the two. Conclusions regarding efficiency are drawn from comparisons based on plant size. Comparisons of firm concentration are supplemented by brief discussions of "supercontrol groups," cartelization, government regulation of business, government ownership and operation in manufacturing, and import competition. Some explanations for the statistical findings are offered.

The general picture that emerges is that plants in the other countries studied are smaller than in the United States, production is less efficient, concentration both by plants and by firms is, more often than not, higher, and monopolistic practices are more prevalent. However, the handicraft sector, which is important in some of the countries examined, is omitted from the comparisons. There are, of course, numerous exceptions and qualifications to these generalizations, and the author does not state his conclusions so bluntly or so briefly.

The study suffers from weaknesses in workmanship. Available primary and secondary sources are not fully or properly used. Some examples of this deficiency may be given from the Canadian literature, with which the reviewer is acquainted. In 20 out of 34 industries Canadian plant size distributions are listed as "not available" although they are published, for most of the industries concerned, in bulletins listed in the government's catalogue of statistical publications. The comparison of plant and company concentration is confined to 5 industries, although the source used for data on company concentration devotes a chapter to this subject and contains comparisons for 96 industries, which, in most cases, could have been put into the form favored by Bain, with the help of supplementary information from published sources. On the non-quantitative side of the analysis, both the text and the bibliography suggest that no books or articles on Canada published after 1959 were consulted, nor the Annual Reports and other reports issued under the Combines Investigation Act. Even a cursory glance at this material should have prevented the astonishing statements found at pages 105 and 154, to the effect that enforcement of Canada's anti-combine legislation is "vigorous" (this is quoted from a misguided secondary source) and that it is a factor in the low ratio of company to plant concentration (no one has ever been convicted on a merger charge in Canada).

The publisher claims on the jacket flap that "a beginning is made here in

the development of a literature in which the industrial structure of different countries is compared on the basis of facts and statistics rather than impressions and folklore." The book is written as if the author believed this claim to be valid; that is to say, the contributions of earlier studies to the subjects under discussion are ignored. They are significant, though not, perhaps, numerous.

All fruitful empirical research in economics involves questionable practices, such as the drawing of conclusions from small or biased samples, the use of "heroic" assumptions, and *ad hoc* theorizing. The problem is to know when an investigator has gone "too far" and this is, of course, a matter of judgment. In my judgment, Bain has gone "too far" in significant respects. For example, conclusions regarding the general level of concentration in a country are based on non-random samples of 19 industries at the three- or four-digit level for France, 16 for India, 7 for Sweden. Even smaller samples are involved in the study of the relation between plant and company concentration. The comparison of efficiency is based on the assumption that in each U.S. industry 70 per cent of employees are employed in plants of efficient size or larger, combined with the assumption that the minimum size required for efficiency is the same, in absolute terms, in every other country as in the United States. The former assumption is derived from the finding in Bain's earlier study that in each of 20 industries examined between 70 and 90 per cent of output came from reasonably efficient plants. The second assumption is backed up by a brief and very inadequate discussion of the possibility that minimum efficient size might differ in different countries.

The monograph gives the impression of having been prepared in haste, with too much of the work, including the examination of source materials, left to research assistants. Nevertheless, it is useful as a compilation of data from a great variety of international sources, and should stimulate further research.

GIDEON ROSENBLUTH

University of British Columbia

R & D: Essays on the Economics of Research and Development. By DANIEL HAMBERG. New York: Random House, 1966. Pp. xiii, 170. \$4.95.

The accelerating growth in research and development (R and D) activity since the end of World War II has, as one might well have anticipated it would, stimulated an accelerating growth in the body of literature relating to the R and D process. Professor Hamberg has been a fairly regular contributor to that segment of the literature which focuses on the economic aspects of the R and D process, and in particular on the interrelationships between market structure and R and D activity. The present volume is a collection of essays which brings together and updates much of Hamberg's previous work in the area, as well as presents some new work relating to the allocation of the R and D budget.

The essays, seven in all, are logically, and in fact, grouped into three distinct parts. The first two essays describe and discuss "the research explosion" and its implications; the next three essays explore the theoretical and empirical arguments that might encourage one to link together R and D activity and

market structure; and, the final two essays present an empirical analysis of the determinants of R and D, and the suggestion of linear programming as a basis for the allocation of the R and D budget.

Much of the material in the book is well known (thanks in part to Hamberg himself) and the virtue in its repetition lies in bringing these materials together in a single volume. Thus, we are once again reminded of the comparatively minor and declining share of R and D effort that is devoted to basic research, the relative preponderance of development activity, the growth in the role of the government as a source of R and D funds, and the growing importance of industrial R and D activity. Hamberg argues that the declining emphasis on basic research, the deterioration in the quality of research, is a potential source of danger to the economy since future applied R and D feeds on present basic research. Yet, the uncertainty of payoff and time lag in payoff will tend to discourage all but a few of the larger diversified firms that can accept the risks, afford to wait for the payoffs, and are capable and interested in exploiting many and varied results in many and varied ways, from undertaking basic research programs. Thus, Hamberg argues, the government may have to play a larger role in the R and D process if basic research is to be supported on a larger scale. This could be done both through the sorts of activities financed by the government as well as through adjustments in the patent system. In particular, there might be a system of awards that would eliminate incentives for minor innovations, or the issuance of dual patents. Finally, government-owned patents might be sold on a nonexclusive basis rather than granted on inventions arising out of government-sponsored research.

Hamberg next discusses the pros (financial strength, ability to diversify efforts, weather hardship, exploit varied opportunities, exploit protected positions) and cons (bureaucratic complexity, large fixed investment in existing operations, inability to enter entrenched markets) of size and market power as influencing research activity. His empirical results lead him to conclude that while size does seem to be a determinant of R and D activity, this varies within individual industries. Through simple correlation analysis Hamberg finds that there is a tendency, albeit an extremely weak one, for R and D activity to be related to industrial concentration, with size playing a slightly larger role. There are, however, wide differences among industries. Hamberg also presents some evidence to support the hypothesis that the large industrial laboratories are likely to be the minor sources of major inventions. He argues that this will be the case because of company quick-profit oriented, low-risk programs, customer- and management-stimulated research ideas, and vested interests. He also argues, not very convincingly, that organized research is handicapped because creative individuals may be unwilling to subjugate their views in favor of a group norm that tends to be most productive of mediocrity through compromise. The potential of interdisciplinary economies and benefits is not considered.

The last part of the book is far and away the weakest. The theoretical arguments and empirical work in attempting to isolate the determinants of R and D (sales, profits, liquidity, government contracts, investment, previous expenditures) tend to be inconclusive and rather unexciting. The use of linear pro-

gramming to allocate and evaluate R and D projects was obvious to others over a decade ago and is no more satisfactory now than it was then, since R and D budget problems still persist in being dynamic problems, under risk, in a nonlinear world.

It seems safe to say that these essays will not set the world on fire nor further disturb the frontiers of knowledge. The book, or at least the first five essays, will be useful to the student of the R and D process in that Hamberg's past work is brought together and coordinated, and some attention (although not enough) is paid to the very important contributions of others, such as Schmookler and Mansfield. The book will not, however, settle any significant debates.

IRA HOROWITZ

Indiana University

The Economic Effects of Regulation: The Trunk-line Railroad Cartels and the Interstate Commerce Commission Before 1900. By PAUL W. MACAVOY. Cambridge: Massachusetts Institute of Technology Press, 1965. Pp. ix, 275. \$10.00.

Paul MacAvoy has written another excellent book of that (happily) growing genre which unashamedly uses economic theory to cast light on the real world. It is a book which is an outstanding contribution both to the "New Economic History" and to industrial organization.

MacAvoy sets himself the task of delineating the factors that lead to the establishment of cartels, and that contribute to their stability and their dissolution. A generation earlier, the decision to write such a book would have surely meant that the author had suddenly acquired access to the previously secret minutes of the cartel meetings. Herfindahl has previously demonstrated that considerable insight into cartel pricing can be garnered from economic inference and outside data. Now, MacAvoy has burnished the tools of economic theory, and produced insight not only into prices, but also the timing of price wars, the identification of the nonconformer and even a convincing indication of the profits and losses accruing to cheater and noncheaters alike.

While everyone *knows* that price differentials between the same grade of a commodity at two locations on the same side of a surplus supply area should represent transport costs between the two points, no one before MacAvoy has used that fact to establish effectively a time series of true transport rates. While everyone *knows* that the market value of a company's shares should reflect changes in its profitability, most students of the "real world" are too preoccupied with establishing the "irrationality" of the stock market to use such price data to date real changes in company affairs: fortunately, that is not true of MacAvoy. The result is that fortunate readers will learn much more about the Eastern truck-line railroad cartels than they knew before and in some cases more than many railroad executives knew at the time. MacAvoy's main conclusion is that the cartel arrangements were clearly unstable prior to the establishment of the ICC. When the ICC began to take action to prevent "unreasonable" rates, the main impact of its regulation proved to be the effective enforcement of cartel arrangements, and when the Supreme Court re-

stricted the rate-setting powers of the Commission, price competition returned again.

A book can be excellent without being what every reader would like it to be. It is possible to find some faults in this book as well. MacAvoy has painstakingly attempted to give the reader all of the statistical and econometric evidence that lay behind his own conclusions, to a degree which is both excessive and bewildering. The reader who wants to challenge the conclusions is well-supplied with ammunition; the reader who wants merely to discover them is less fortunate. At a more fundamental level, MacAvoy has not done all the things this insatiable reader would have liked. For example, the hypothesis that cartel success or failure was determined (or affected) by changes in transport costs or in capacity utilization is treated only in two long footnotes on pages 65 and 195, and in the latter case only in support of MacAvoy's conclusion that the ICC was the predominant cause of the cartel stability in later years. In fact, except for his demonstration that cheating was frequently profitable he gives us surprisingly little insight into why cheating occurred at the particular time it did and by whom. For example, he shows that the N.Y. Central suffered least from breakdowns in the cartel, but it was not an outstanding cheater, while the Erie and the B&O which were particularly hard hit by price wars, cheated as much as anyone. The stocks of the latter roads were in a general decline during the period while the Central stockholders prospered. It is almost as if the prosperous railroads were willing to cooperate as long as stockholders were happy while other roads used the temporary profits from cheating to stave off stockholder discontent or increase liquidity in an imperfect capital market.

No one can satisfy every reader, and this reviewer's gratitude clearly outweighs his disappointments. MacAvoy has done an outstanding job of demonstrating the light that can be cast on practical problems by the sensible application of economic principles. We can only hope that he (and others) will shine that light on other problems soon.

PAUL H. COOTNER

Massachusetts Institute of Technology

Defense Purchases and Regional Growth. By ROGER E. BOLTON. Washington: The Brookings Institution, 1966. Pp. xiv, 189. \$2.50.

As the title implies, this study is concerned with the impact of defense expenditures on regional growth. The units under consideration are the states during the period 1951 through 1962. The conclusion, as expected, is that defense expenditures do influence growth and that the impact on total income is more significant than the impact on per capita income.

The author's framework of analysis is an economic base (foreign trade multiplier) model in which exports are the major exogenous activity. The main sources of data are annual Department of Defense contract award data, income estimates by states, and wage and salary information by state and industry groups. Given these data, the share of federal defense spending as a component of export activity levels is taken as a measure of importance. In

turn, changes in the level of total income and per-capita income are examined in terms of changes in defense activity.

The immediate empirical problem is how to estimate the exogenous income of a state and the defense spending in a state. Three estimates have been made for exogenous income. In all three cases property income and transfer payments are included. Manufacturing and agricultural income are assumed as exogenous, *a priori*, in one case. In the other two cases exogenous income is determined on the basis of location quotients. Defense spending consists of three groupings: military payrolls, civilian defense department payrolls, and procurement purchases. The first two are estimated directly for each state, although not without some digging. Procurement spending, which constitutes about two-thirds of all defense spending, is more difficult to estimate by state. Only prime contract award data are available by state and these do not show industry groups. The nasty problems are to account for: (1) the fraction of prime contracts which accrue to the state as income; (2) the income generated by subcontract work in a state, regardless of the location of the prime contractors; and (3) the estimation of non-subcontract interindustry purchases from other manufacturers.

The author's method of estimating procurement spending on a state-by-state basis is only partly satisfactory. On a "share of the nation" basis each state's share of total procurement in any year consists of three components: (1) the share of contracts awarded, lagged to account for delays between contract awards and work done; (2) the share of wages in "defense related" industries; and (3) the share of wages in all "other manufacturing" industries. Each component is weighted by the estimated value added within the state with the weight sum equal to one. The author estimates a value of .5 to a state's share of contract awards, i.e., half of a typical contract represents value added by the prime contractor. For "defense related" industries, three alternative values are calculated .1, .2, and .3. The last term, the share in other manufacturing, takes up the residual .4, .3, or .2, depending on the values used for the "defense related" industries.

The industries in the "defense related" category include: Aircraft and Parts, Ordnance, Ships and Boats, the electronic industries, and other such industries. Yet, these are the same industries that receive the vast majority of prime contracts. This raises two problems. First, prime contract awards are somewhat double counted. Second, since these are essentially the same industries that hold prime contracts, the coefficient for value added also should be .5. Use of this value, however, would leave nothing for the third component, "other manufacturing." Thus, while it seems inconsistent to assign "defense related" industries values of .1, .2, or .3, it does avoid this problem. It means, however, that analytically any distinction between the prime contract component and the defense related component is blurred.

The author's overall findings seem quite reasonable. During the period 1952 to 1962 the Pacific, Mountain, South Atlantic, and New England states have had the highest share of their aggregate income growth dependent upon defense expenditures. The two areas where the impact exerted a negative

influence were the Middle Atlantic and East North Central states. In large part this shift reflects the changing pattern of military requirements towards aircraft and missiles. While this geographic pattern reflects the total impact, prime contracts tend to be even more concentrated in the first four state groups mentioned, while the Middle Atlantic and East North Central gain in the sub-contracts or other input requirements. These same geographic patterns also show up in the special Census of Manufacturers report, *Report on Shipments to or Receipts for Work done for Federal Government Agencies and Suppliers* (1963, MA-175), published after Bolton's work was completed.

Given the growing interest in regional development policies at the federal and state and local level, Bolton's analysis of one of the largest sources of autonomous regional income, military expenditures, is extremely welcome. Further, the author is to be congratulated for ferreting out hard to come by data. Both students of regional economics and defence economics will find this a useful work.

CHARLES M. TIEBOUT

University of Washington

Economic Report on Mergers & Vertical Integration in the Cement Industry.

Staff Report to the Federal Trade Commission. Washington: Supt. Docs. 1966. Pp. xiii, 123. 45¢.

Up-to-date information on an important industry is always valuable. The Bureau of Economics of the Federal Trade Commission has put together a competent survey of the structure and performance of the cement industry—a survey prompted by concern over the extensive mergers in the industry and possible action against such mergers under Section 7 of the Clayton Act.

There were 48 producers of cement in the United States in 1966, the number having fallen from 72 in 1946, despite the entry of 13 new companies. Mergers account for the reduction in numbers. The relevant market, however, is not national but local or regional. The structure of these markets is oligopolistic; out of 51 identified "regions," only 3 have a largest-four concentration ratio of less than 50 per cent (these account for 11 per cent of total U.S. output), while 34 regions have concentration ratios for the largest four producers of over 75 per cent. Yet concentration in the markets does not seem to have changed very much in recent years, notwithstanding numerous acquisitions. The reason is that mergers have for the most part been "extension" mergers—acquisitions by firms in one market area of plants or firms in another market area. There have been very few "horizontal" mergers within market areas. Producers in one area have also frequently entered other areas by building new plants there.

The report views vertical mergers with alarm. Though several producers of ready-mixed concrete have entered the production of cement in recent years, most vertical integration has come about through forward merger—acquisition of ready-mixed concrete companies by cement producers. In 1966, 19 cement companies had acquired ready-mixed companies, almost all subsequent to 1959. The "tied" concrete producers consumed 7 per cent of all cement pro-

duction, of which 4 per cent came from their affiliated cement companies and 3 per cent from nontied suppliers. These figures may seem trivial, but the report views them as developing trends; in some local markets the percentage was much higher, e.g. in New York where consumption by affiliated concrete producers reached 29 per cent of total cement shipments.

What problems is the trend toward vertical integration between cement and concrete production likely to create? Vertical integration may reduce the competitiveness of markets and lead to a worsening of overall economic performance when it extends a pre-existing monopoly into adjacent markets, when it creates an integration "squeeze" in previously competitive markets, when it forecloses supply or market access to a competitive sector of an affected market, or when it raises additional barriers to entry. There is no clear evidence that any of these effects have actually occurred, though the report discerns the threat that all of them will. So far the effect of acquisition has been redistribution of supply and market outlets rather than foreclosure, and the total percentage involved is too small to permit an overall "squeeze" on non-integrated manufacturers of ready-mixed concrete. One difficulty in assessing the probable consequence of vertical integration is that ready-mixed concrete is itself a new industry; it had scarcely become well established before cement makers began acquiring parts of it. These producers formerly sold cement to wholesalers and building contractors; now the integrated firms will sell concrete to building contractors. Will this enhance their market power? A lot depends on the scale economies and entry conditions at the ready-mixed level, and information on this point is sketchy. The report does quote the opinion of some cement companies that they could not "afford" to enter ready-mixed manufacture except by acquisition, and that it would require "\$3-5 million" to enter by internal expansion, but does not explain how the more than 300 existing producers of ready-mixed concrete managed to "afford" it. Full integration between cement and concrete would no doubt increase the difficulty of entry into the cement industry, but we do not know how much.

The recent merger movements, horizontal and vertical, do not seem to have worsened economic performance in the cement industry as yet. The report shows that capacity has grown apace, keeping well ahead of demand; that profits have declined to quite modest levels in recent years; that prices have declined since 1960 and have shown signs of increased structural flexibility; and that producers have provided "faster and more convenient service to customers" in the postwar years (p. 63). Nor has the reduction in the number of cement producers resulted in markedly different structural conditions within the relevant markets. The case against mergers thus appears to rest on the general proposition that acquisition rather than expansion by internal growth in a context of oligopoly is very likely to strengthen monopoly materially—if it proceeds far enough. This is the view embodied in the "incipiency" provisions of the Clayton Act, which is designed to deal with tendencies and probabilities as well as with established monopoly.

JAMES W. MCKIE

Vanderbilt University

Utility Regulation: New Directions in Theory and Policy. Edited by WILLIAM G. SHEPHERD AND THOMAS G. GIES. New York: Random House, 1966. Pp. xii, 284. \$2.95.

This collection of nine papers on telephone and electric utilities is significant chiefly for not presenting new things, and overlooking important developments that are new.

Professor W. Haber's sense that inadequate earnings allowed by commissions have discouraged innovation neglects 85 years of remarkable advances. Though "continuous surveillance" of utility rates by commissions is presented as new and desirable, Twentieth Century Fund's *Electric Power and Government Policy*, written in 1940-42, found "something fundamentally wrong" with secret negotiations. The statement that "The era of suspicion, when both the regulated and regulators viewed each other as mortal enemies, is over," is inconsistent with the Dixon-Yates episode of 1953-56, the fierce struggle over generation and transmission cooperatives, and the deep antagonisms uncovered in the hearings of 1965 on the Smathers-Holland Bill (S. 218) to cut Federal Power Commission's jurisdiction over wholesale power rates.

Professor Shepherd apparently concurs with "critics" that the "best" regulation is "slow and ineffective" and "least calamitous." The basis is an unsupported thesis that regulation breeds inefficiency and unnecessary capital intensity. His estimated saving of "at least" \$2 billion by cutting reserves 8 per cent in 1960 is high by a factor of 3 or 4 if applied to the oldest generating plant. The statement that profits regulation succeeds mainly in deflation ignores FPC rate cuts since 1961. The explanation for regional differences in electricity rates neglects government competition.

Professor J. R. Nelson's model for indexed capital overlooks the historical success of utilities in raising capital, and the investor's continuous option to sell securities as price levels fluctuate. The discussion of marginal cost pricing omits the possibility of use patterns not changing correspondingly, or of off-peak becoming peak loads. It should explain why the Ontario Hydroelectric Commission is moving in the opposite direction.

Professor Gies, stipulating cost-plus pricing, proposes incentives and penalties to achieve "the proper allocation of resources among alternative uses, rather than mere profit limitation." Cost-plus does not explain the spread of rates of return from under 5 per cent to above 10 per cent within and among States. The need for incentives is contradicted by history. Improper resource allocation is unproven and inconsistent with the regulatory theory of the competitive analogue.

Professor C. E. Troxel, discussing telephone regulation in Michigan, inconclusively questions metropolitan rate schedule uniformity. He characterizes the Michigan commission as "tough" for reducing company requests, and cannot believe that there is tactical overasking. But his own statistic that allowed profit rose during 1948-61 from 6.0 per cent to 8.0 per cent indicates little toughness. Professor Ben Lewis provides a wise sermon urging companies to be philosopher-kings by surpassing commission minima, but it could as well have been written in 1940.

Professor G. J. Stigler's title is, "What can regulators regulate?" in electric-

ity. He is introduced as "a veteran tweaker of noses and ruthless enemy of bad logic." His initial error is the dictum that regulatory literature "touches seldom and lightly on the most basic question one can ask about regulation: does it make a difference in the behavior of an industry?"—for this question has dominated the literature for 60 years. The proposition that "innumerable" regulatory actions are "conclusive" of the desire to regulate is a non sequitur—a major criticism is that commissions don't want to regulate. Several errors of fact are contained in the statement that "professional" writers "hail" the beginnings of "effective" regulation from 1907, footnoted by the 1940 Brookings study, *Government and Economic Life*, and Twentieth Century Fund's study (*supra*). Only State commission regulation of electricity dates from 1907, with the cited volumes demonstrating this regulation to be largely ineffective. An oddity is data no more recent than 1937, despite much better data available since. Regulation is incorrectly said not to be intended to protect commercial customers.

Stigler's experimental design compares gross revenue per kilowatt-hour, with and without State commission regulation. A crucial flaw results from thus disregarding differences in proportions of industrial, farm, and residential loads and such elements as electric cooking, water, and space heating. Use of typical bills would have been sounder. The design error is itself due to a more basic defect, the absence of qualitative investigation and analysis. Twentieth Century Fund's study, for example, had already performed, with comparative thoroughness and wisdom, the comparisons attempted by Stigler, and had found significant differences where he could not. He might thus not have written that his confreres have "assuredly" not faced up to the problem of measuring the effects of regulation, that their judgments are "suspect," and that "They never question the importance of (effective!) regulation."

Utility Regulation omits mention of government competition as a regulatory device, although this arena is where comparative effectiveness of commission regulation is best measured. Though 40 years of regulatory frustration with reproduction cost was largely relieved by the *Hope* case (1944), there is little analysis of subsequent influence on regulation. There is nothing on the vital *Colton* decision of 1964 (*FPC v. Southern California Edison Co.*, 376 U.S. 205) which affirmed FPC's view that the interconnected engineering network of utilities is under its wholesale power jurisdiction, despite intrastate company boundaries. The industry's reaction at the 1965 hearings on S. 218—the most significant insight into the regulatory process since the 1930's—is overlooked. The postwar competitive role of rural generation cooperatives is unnoted.

Department of Commerce, Washington, D.C.

Transport and the Economic Integration of South America. By ROBERT T. BROWN. Washington, D.C.: The Brookings Institution, 1966. Pp. xiii, 288. \$6.00.

This book is concerned with what might be done to improve intercountry transport in South America in order to further the aims of the Latin American

Free Trade Area (LAFTA). In other words the author accepts the intercontinent common market approach as his basic assumption and his treatment of transport problems is conditioned by this assumption. A second assumption, which he also favors as a goal, is balanced urban development and the avoidance of urban gigantism.

Very briefly, the argument is that although South America may be a continent (almost no consideration is given to Mexico which is also a member of LAFTA, or to Central America) topographical features make road and railroad interconnections very costly so that to secure integration, reliance must chiefly be had on ocean and air transport. This broad generalization is not so valid for Region I, the industrial section of Brazil and Argentina (in rather old fashioned geophysical terms referred to as the "Industrial Heartland" of South America) and Region II the "Supporting Hinterland," which embraces the whole of Paraguay and Uruguay, that part of Argentina not included in Region I, the Brazilian Federal "Distrital" and provinces of Mato Grosso, Goiás and Rio Grande de Sol and the Bolivian department of Santa Cruz, where roads and internal water ways would serve. This leaves the other seven regions of South America more or less isolated from Regions I and II and from each other, although it is stated that the main problem resides in the lack of sufficient and low cost ocean liner service for general cargo from Region VI (Colombia and Venezuela) and Mexico to and from the other countries. Main attention, therefore, is directed to the desirability of securing such service. While such service would aid in generating more trade, it is recognized that the prior existence of a considerable volume of such traffic (at least potentially) is probably a condition for the provision of this service without heavy subsidies, and that the movement of general cargo is today very small. An alternative—air transport—it is argued, favors excessively large cities, though this has not been true in Colombia.

The main practical recommendations are the creation of new LAFTA maritime transport agencies—a shipping conference composed of shipping companies of LAFTA and of foreign countries serving this area and a LAFTA regulatory maritime commission. Traffic between the LAFTA countries would then be reserved to the conference members. The adequacy of such measures to achieve the purpose in mind appears to be doubtful, even to the author. He recognizes that to date "the maritime transport problem has been looked upon as one of protecting LAFTA ships rather than as one of improving maritime service" and that "inefficient ports and undisciplined port workers represent, at present, the single most important obstacle in this transport sector to economic integration in South America," and it is questionable whether these new administrative agencies can resolve these problems.

Finally, the completion of the Pan American Highway is listed as a prerequisite, though it is admitted that even this will fail to secure integration unless existing "bureaucratic controls and restrictions" on trade are removed. Curiously enough, the highly ambitious and costly proposed road from Venezuela along the eastern slopes of the Andes to Brazil is not mentioned except by implication as it is stated, quite correctly, that road transport along this route would present overwhelming problems.

Transport is evidently only one element, and not the most important one, in increasing trade between Latin American countries. Perhaps a more fruitful approach would be to follow up the clue contained in the statement "economic integration in South America will be significant solely if it is successful between Brazil and Argentina," though one might question the word "solely." This bilateral approach could be applied to other groups of countries, such as Colombia and Venezuela, instead of assigning to the latter grouping the rather startling role of the "Texas and Louisiana" of South America (because of their oil production), and the transport problems that Dr. Brown is struggling with would be enormously eased. The Declaration of Bogotá subscribed to by Chile, Peru, Ecuador, Colombia, and Venezuela in 1966 at least opens the door to the study of the desirability of smaller regional groupings. However, it would not be fair to tax Brown for failing to discuss possibilities he expressly excludes from his frame of reference. Within the limitations the author sets himself, the treatment is provocative and the collection and presentation of the statistical material is skillfully done. What is clearly brought out is that a transport program necessarily depends on what wider economic goals and programs are adopted.

LAUCHLIN CURRIE

Universidad Nacional, Bogotá, Colombia

Transportation and Economic Policy. By JOHN B. LANSING. New York: The Free Press; London: Collier-Macmillan, 1966. Pp. xv, 408. \$7.95.

For a relatively short book, as textbooks on transportation go, 400 pages, Professor Lansing provides an excellent and broad view covering both intercity and intracity transportation of people and freight. He undertakes to look at transportation in microanalytical terms, theoretically, in 70 pages, and empirically in many other pages scattered among the sections on rail, highway, and the other modes. More than usual space is devoted to the point of view of economic development, with five principal country cases and several minor ones, containing both historical material and present day situations. There is a reference desirable but too brief to location theory and analysis and to transportation's role as just one of the inputs in production with significant possibilities of substitution of other inputs for transportation and the reverse. There is a concise and surprisingly complete coverage of government regulation, from both historical and analytical viewpoints. Costing is considered in its more general aspects. The book has a solid analytical approach and a good display of the relevant analytical methods, presented almost entirely verbally, there being only seven graphs and five equations.

The author does a good job of noting the limitations placed upon analysis by a dearth of statistics relating to some significant features of transportation in America and by the almost complete absence of meaningful data in underdeveloped countries. There is appropriate recognition of the difficulties of estimating demand elasticities and social benefits or costs, and of choosing the proper interest rates for use in public investment decisions. There might well have been more concerning the uncertainties in dealing with measurement of the capacity of transportation facilities and the quality of transportation ser-

vice. The problems in developing operationally useful bases for allocation of joint and common costs, a matter of universal importance in transportation, likewise need more emphasis.

There is a significant weak spot in coverage with respect to prices. Average revenue per mile figures, even by commodity or other particular groupings, do not provide enough evidence on prices to indicate the nature of market structures, the extent of discriminatory pricing practices, and the nature of carrier responses to changing demand and supply factors. The widespread practice in connection with intercity passenger transportation of providing first class and coach services with differentiated prices is not portrayed and analyzed. In the field of freight transportation, the more complex differentiations between prices for particular commodities, routes, and consignment sizes (less-than-car or truck load, carload and truck load and multiple carload) again are passed over. From the point of view of the economist, some of the recent European developments in revamping freight rate patterns, with greater consideration given to marginal costs, are highly significant. The major restructuring of U.S. railroad freight rates with the introduction of any-commodity carload rates for forwarders, and then piggy-back and multiple-car or train-load rates, are equally interesting. The role of price in allocation of resources to various transportation operations is too important not to be well covered.

A Production Model for Wheat and Feedgrains in France (1946-1961). By BERNARD OURY. Amsterdam: North-Holland, 1966. Pp. xvii, 306.

The major concern of this book is "supply response" for wheat and feedgrains in France. This is expressed, in the core of the book, through the fitting of regression equations using time series data, with grain acreage, yield, and output, in turn, explained by a variety of explanatory variables. The usage of the term "model" here appears to mean a final version of a single equation regression which the author feels has the best properties of all the alternatives examined for a specific dependent variable. The model is thus a rather elementary construct, and, as the author notes in his preface, "generally this essay does not contribute any new theoretical breakthrough," since it essentially involves straightforward applications of least-squares.

In terms of organization, there are (1) a set of introductory chapters presenting background material on relations to be investigated and variables involved; (2) the regression results, with a chapter, respectively, for wheat and feedgrains, followed by an evaluation chapter; and (3) a forecasting application of the results directed to the consequences of alternative common market grain pricing policies.

Several limitations are noted in the introductory section: Only 16 observa-

tions were available on each grain category (covering the period 1946-1961) and only linear forms were used. Explanatory variables include measures of weather, price, and "technology." A number of weather variables are described, with ultimate reliance placed primarily on an index involving precipitation and temperature and on a measure of the severity of the winter. Similarly, a variety of price variables is introduced, with final choices involving wheat (or feedgrain) price relative to the wholesale price index and wheat price relative to feedgrain price. These price relatives are related to "transitory and permanent components" of production, respectively (pp. 10, 113, and 160); the terminology here is geared to ease of substitution in production. (Such terminology is fashionable, at any rate.) Prices are lagged, affording a rationale for single equation estimation, in addition to the author's appeal to authority (Wold, Waugh). The author attempts to measure technological change by fertilizer use. The notion of technological change shifting a supply curve is reasonable, but the use of fertilizer as a proxy is suspect at best; and the author's explanations—if anything—make matters worse (pp. 44, 50, and 51). Among other difficulties here, there is no distinction made between changes in underlying production functions and changes in input levels and proportions reflecting input price changes; and the final form of equation employed includes a production input and can be viewed as a blend of supply and production function.

The introductory material also includes a number of arguments on farm firm behavior and aggregate supply along the lines of doctrines propounded by Willard Cochrane, and there is a useful summary of French price and income policy for grains.

The regression results, in summary form, include the following points: A great many alternative equations have been fitted and presented, with the author displaying a good deal of persistence and some ingenuity in extracting maximum information from limited data. The marginal return to the reader for many of the alternatives presented, however, is rather low: In many cases, there is little difference in R^2 , and in meaning, among alternatives. The results are usually quite "reasonable." Thus, focusing on output equations with highest R^2 , we find for wheat that the weather indexes (as indicated above) have negative coefficients and the price variables have positive coefficients, as expected; the fertilizer variable, too, has a positive coefficient. For feedgrains, all the variables employed (winter effect, prices, and fertilizer) have coefficients of expected sign and are significantly different from zero.

The reasonableness of results is to some extent imposed by selection. This is defended as a virtue by the author (p. 164): "Regressions have been revised until the signs of the coefficients conform to reality and the main statistical tests are satisfactory." Virtue, if overdone, can be a vice. Certainly, some experimentation is called for in exploring economic relationships; but given enough alternative measures and computer time, perhaps *any* a priori "reasonable" hypothesis can obtain apparent confirmation.

A good deal of effort is devoted to considering direct estimates of output (based on the output regressions) versus indirect estimates (consisting of estimated acreage times estimated yield). The reason for this is not particularly

clear since (as one might expect) the direct estimates are better in terms of explained variance (based on applications of data given in the text). Estimates of price elasticities are obtained, and it is of interest that they are rather high, with both deflated wheat and feedgrain elasticities being approximately unitary and above previous U.S. estimates (p. 178).

In the final section of the text, the author applies the regression results to develop forecasts of the impact of alternative common market price policies for grains. The alternatives may be labeled high, medium, and low, for simplicity; results depend, in effect, on the elasticity estimates obtained. It turns out that the EEC has since selected essentially the medium policy (with a wheat price about 6 per cent above the current French price and 11 per cent below the German price) to go into effect by July, 1967. The author's forecast (for this policy) of a 5 per cent increase in French wheat output and a 12 per cent increase in feedgrain output thus yields some opportunity for checking a forecast against reality.

In retrospect, a major criticism of the book is that there is not enough reliance on economic theory (of the orthodox variety, at any rate). Thus, we are told that if product prices fall, farmers "have to produce more in order to break even" (pp. 17 and 50) and are advised to do so by "drastically increasing fertilizer consumption" (p. 212). This may be in line with some of Professor Cochrane's ideas, but it yields a rather unusual sideways V-shaped supply curve: If prices *change*, output increases. (Perhaps there is implicit here the notion that farmers are not maximizers, and the shock of falling prices forces more effective behavior. As a minimum, this is not particularly orthodox doctrine.)

Again, the author focuses on acreage and yield as *determinants* of output (see, for example, pp. 73 and 175). Of course, output is identical to acreage times yield (or output over acreage). Indeed, paraphrasing Gertrude Stein, an identity is an identity is an identity. Now, yield, in other terms, is the average product of land. Average product may rise because of technological advance, or because of changing relative prices of factors, or because use of land is restricted by government. The results may look the same numerically, but the meanings attached thereto will differ. Parenthetically, as every economist knows, maximizing yield is not particularly economic; assuming two inputs and constant returns, marginal product of the other factor will equal zero. Further, using yield as an indicator of "productivity" is akin to (and as wrong as) using average product of labor as the same sort of indicator. Perhaps an occasional reminder of such things is in order.

IRVING HOCH

University of California, Berkeley

The Supply Responses of African Farmers. By EDWIN DEAN. Amsterdam: North-Holland, 1966. Pp. xiv, 174. \$7.00.

Edwin Dean's short book, in spite of its somewhat grandiose and misleading title, is an interesting attempt to quantify several crucial aspects of African agriculture. It is quite well written and has an important message for specialists concerned with Africa, agriculture, or economic development. In particu-

lar, it sheds some light on the elasticity of supply for cash crops, the characteristics of the labor supply function, and the "social factor" as a determinant of market price in Africa.

The geographic base for Dean's book is Malawi in southeast Africa. Most of the time he is specifically concerned with tobacco and tobacco producers in that country, and Chapter 1 is devoted exclusively to the recent history of Malawi and its economy. However, the significance of the book is not as limited as the one-country, one-commodity empirical base might imply. For in Chapter 2, Dean presents a useful approach for analyzing the largely subsistence agriculture which is typical of much of sub-Saharan Africa. In his framework, a clear distinction is made between the types of output for which growers have revealed a desire, i.e., home goods, cash goods, and leisure, and the types of inputs which are necessary to obtain these outputs, i.e., home-goods production, tobacco production, leisure, and other wage-earning activities in the nonsubsistence sectors. Using these categories, and the Hicksian notion of income and substitution effects, Dean analyzes the direction and magnitude of various types of farmer responses to price. For example, he argues that a rise in wage rates in nonfarm (or plantation) activities will cause a shift in labor and thus a decline in tobacco production. He is clearly not a believer in the concept of zero marginal productivity for labor in agriculture.

A theoretical chapter sets forth in a provocative way the complexities of "rational" economic behavior as seen by the African peasant farmer. It is particularly good in underscoring the employment and other interrelationships between the agricultural and nonagricultural sectors in a labor-scarce economy. Because of this relative scarcity, however, both the theory and its implications are significantly different from much of the recent writing on labor-surplus economies such as India and Pakistan.

While the analytical framework for agriculture presented by Dean has several advantages, the specific conclusions he draws for Malawi are, in part, dependent on some rather special assumptions. For example, the sharp distinction which he makes in the analysis between home-consumed goods and cash crops plays an important role. In assessing the implications of a rise in income from any source, he argues, "Since the income elasticities of leisure and home goods are both positive, by assumption, a net increase in the consumption of each . . . will occur. Since these goods can be consumed only if the grower and his family produce them, more [resources] . . . will be allocated to [their] . . . production. Therefore, the amount of land and labor allocated to . . . tobacco will necessarily decline" (p. 31). But this decline in tobacco supply is "necessarily" so, only if farmers cannot purchase (or barter) "farm-produced" consumption items. Certainly at the margin this trading possibility must exist, and hence one of his distinctions, and possibly one of his conclusions, remains open to question.

In the empirical portion of the study, Dean presents an excellent review and comparison of other estimates of agricultural supply functions from less-developed countries. He then uses a variety of first-difference models to show that lagged prices of the various goods described earlier are indeed an important determinant of fluctuations in Malawi tobacco sales. In these models,

Dean creates estimates of "expected" prices by using a weighted average of tobacco prices for three years; yet, interestingly enough, he avoids the use of a distributed-lag formulation, even though the tobacco price is often the only significant variable besides the weather. In addition, he shows an unusual concern about degrees of freedom, even though the time series used in the study exceed 30 years. Finally, the write-up of the statistical analysis is cumbersome and difficult to follow. While direct comparison with other studies is difficult, his results seem to show a relatively high price response on the part of Malawi tobacco growers, with supply elasticities on the order of 0.5.

In analyzing the trends (as opposed to fluctuations) in tobacco sales in the last 35 years, Dean shuns the use of prices as an explanatory variable. He argues that cost-reducing technical change and incentive effects of imported consumer goods were the prime factors in sustaining the two per cent annual growth. While these arguments are consistent with the data and are presented in a convincing way, several other hypotheses might have served equally well. For example, it would have been useful to have considered increased labor-land ratios as an explanation for increased yields—especially given the concern with the labor input in the monograph.

The final chapter deals with social forces as determinants of market prices in Africa. Three controlled experiments are reported, two from southern Malawi and one from the Congo. While the market discrimination chapter is obviously an appendage to the main portion of the book, the results are interesting and are occasionally humorous. One set of experiments was intended to discover whether members of one tribe sold at lower prices to their own tribesmen than to members of other tribes, while the second tested "whether young women sold at lower prices to young men than did old women" (p. 102). The general conclusion of all these tests was that social groupings were not an important determinant of price.

The most important contribution of Dean's volume is the readable theoretical chapter which provides a much-needed supplement to the recent literature on two-sector economic development models. In addition, the empirical estimates add to the growing evidence that prices and other economic variables are prime determinants of production, even in traditional agricultures.

Harvard University

Labor Economics

Unemployment, Money Wage Rates, and Inflation. By GEORGE L. PERRY.
Cambridge, Mass. and London: Massachusetts Institute of Technology
Press, 1966. Pp. xv, 143. \$6.00.

In recent years, beginning with the pioneering study by Professor A. W. Phillips in 1958, there have appeared a number of empirical studies to explain the behavior of wage rates. The present book by George Perry is a further contribution to our understanding of this phenomenon. The author begins by giving a brief survey of the important past publications which have been concerned mainly with the economies of the United Kingdom and the United

States. He criticizes these studies, especially those by Phillips and Lipsey, on the grounds that they are limited to annual data and thereby probably obscure short lags between the relevant variables. In the case of the United States, on the other hand, Perry points out the contradictory results obtained by W. G. Bowen and the present reviewer regarding the role of unemployment in determining wage changes. Perry believes that in this latter case an excessive concentration on one, rather than more, explanatory variables may be the reason behind this contradiction. Consequently, he advances the hypothesis that the changes in wage rates are determined by more than one variable: he identifies these as the level of unemployment, profits, cost of living, and the state of expectations (i.e., the direction in which the explanatory variables are moving). He sets out to verify this hypothesis by considering the postwar behavior of wages in the United States.

The author uses quarterly data and employs primarily the least squares regression methods. In order to point out the explanatory power of each variable, he builds up his analysis step by step starting with the relationship between wages and unemployment and adding cost of living and profits as explanatory variables. The final equation relates wage changes to the level of unemployment and profit rates and to the changes in the cost of living and in the profit rate. Perry finds enough evidence to support his hypothesis; R^2 for his final equation equals 0.879. The main policy conclusion the author derives from this equation is that there is little hope of combining low unemployment rates with price stability. On the basis of a 3 per cent annual growth in productivity, and profit rates stable at their 1947-60 average level, price stability would imply an unemployment rate of 6.4 per cent. The author discusses finally various policy measures that may be undertaken to change the structural relationship with a view to lowering the rate of unemployment that may be consistent with price stability. These measures include changes in corporation tax rates, accelerated depreciation allowances and other tax incentives, fostering competition, avoiding economic fluctuations, etc. However, these long-term measures would hardly change the basic relationship in the short period or even the medium period.

How far is Perry's extended equation a better explanation for wage changes in the United States than the earlier studies? The R^2 for his equation, with four explanatory variables, at 0.88 is only slightly higher than the corresponding figure of 0.80 obtained by the present reviewer in relating wage changes to only the level and the rate of change of profits. Considering the previous studies, perhaps it would have been better if the regression analysis had started with a single relation between wage changes and profit rates and then extended step by step to include other variables. But Perry appears to have a bias in favor of unemployment rather than the profit variable as the more natural (or the primary) explanatory variable and discusses the policy questions more in the domain of varying the (uncertain) relationship between wages and unemployment than the (less uncertain and more maneuverable) relationship between wages and profit rates. Finally, it would certainly have reassured the readers more if the question of possible correlations between the explanatory variables had been considered explicitly and shown as insignif-

nificant. Notwithstanding the above, Perry's book is a useful contribution on the subject, not only because it contains a valuable review of the past studies, but also because it tries to extend the analysis on a more general basis than hitherto.

RATTAN J. BHATIA

International Monetary Fund, Washington, D.C.

Public Contracts and Private Wages: Experience under the Walsh-Healey Act.

By HERBERT C. MORTON. Washington, D.C.: The Brookings Institution, 1965. Pp. x, 140. \$3.50; paper, \$2.00.

Wage Policy under the Walsh-Healey Public Contracts Act: A Critical Review. By CARROLL L. CHRISTENSON AND RICHARD A. MYREN. Bloomington and London: Indiana University Press, 1966. Pp. xiii, 239.

The time: 1935. The event: the National Industrial Recovery Act has just been declared unconstitutional. The response: Secretary of Labor Perkins tells Roosevelt that the minimum wage and maximum hour features of the NIRA can be partially salvaged by a law applying them solely to government contracts. Result: the Walsh-Healey Act of 1936.

These two excellent books describe the background and effects of this legislation. The Morton book is a model of clarity and organization; the Christenson and Myren book is somewhat less so. However, the latter authors assume a more difficult task in that they attempt a painstaking statistical analysis of the law's wage impact.

Although Walsh-Healey was passed in 1936, it has basically been administered as a supplement to the Fair Labor Standards Act of 1938. Both books suggest that if Perkins and Roosevelt had felt that the FLSA would be held constitutional, the Walsh-Healey Act would never have been proposed. But no matter . . . it has stayed on the books.

Although a supplement to FLSA, WH's legal provisions are significantly different, and herein lies an interesting tale in the history of government intervention in the economy. FLSA minima are legislated by Congress; WH minima are determined by Secretary of Labor fiat (since 1952 subject to judicial review). FLSA minima are nationwide in scope whereas WH's are restricted to a very fuzzy concept of "locality." Also, WH has certain extra legal exemptions (such as the statutory minimum of a \$10,000 contract and the exemption of subcontractors) which complicate implementation.

Morton makes painfully clear the tremendous morass of formalism and legalism that has engulfed WH—a virtual bureaucratic nightmare or delight, depending upon your perspective. Labor and business have fought over every conceivable ambiguity in the law, of which there are several. The Congressional dictate to the Secretary of Labor is a natural for disputation: to determine "the prevailing minimum wage." This is not the European concept of a "living wage" or a "fair wage." As Morton points out, this makes the Secretary "a wage finder, not a wage fixer." But how to define "the prevailing minimum" has, as might be expected, plagued the administrative branch of government. Unions have maintained that it means the union contractual rate; business representatives have insisted that it means the lowest end of the in-

terquartile range in BLS surveys. The Secretary of Labor has tended to compromise on the median rate in BLS surveys, naturally satisfying neither of the parties.

Christenson and Myren attempt a detailed analysis of the law's impact in four industries. Morton's study centers more on the procedural aspects of the law. But both books agree that the wage impact has been slight. They feel that very few workers have been affected and that there have been few indirect effects in terms of intra-firm, intra-industry, or inter-industry adjustments.

Both books raise, but do not sufficiently answer, the question of whether the law should be amended or repealed. Both express a dissatisfaction with the law and call it "ineffective," but neither adequately defines what an "effective" law would be. They both convey the feeling that if there is such a law *it should be doing something*, but that the predominant thing this law is doing is contributing to bureaucratic red tape. Certainly one goes away from these two books with the feeling that the administrative cost to government, business, and labor far exceeds whatever "good" this law may have accomplished for a few workers, or "bad" it may have imposed on a few business firms.

In my opinion, one procedural aspect of the law that merits much more attention than it received in either book is the political and economic consequence, both potential and real, of lodging so much authority in the executive branch of government. *So much* is left to the discretion of the Secretary of Labor. It is not only up to the Secretary to determine "the prevailing minimum wage," but also to decide for which industries and localities such "prevailing minima" should be established. We live in an age in which the power of the executive branch of the federal government is being exercised imaginatively and threateningly towards both business and labor. The power of the Secretary of Labor to issue or change a "prevailing minimum wage" is a natural lever for use by the President in his efforts to exert administrative pressures against individual industries, firms, or unions. The FLSA is a clear infringement on the free enterprise principle of letting market forces be determinate, but at least FLSA simply sets uniform standards for all industries covered, with the wage minima established by Congress. WH goes one step further in relying on flexible executive discretion to be determinate. I shudder at the thought of WH procedures being adopted for FLSA. The implications and propriety of such extreme reliance on executive discretion in setting minimum wages is unfortunately not considered in these otherwise excellent and complementary books.

RALPH C. JAMES

University of California, Davis

Women in the Soviet Economy. By NORTON T. DODGE. Baltimore: Johns Hopkins Press, 1966. Pp. xviii, 331. \$10.00.

This thorough book surveys the high level of educational achievement and labor force participation by women in the Soviet economy. The basic explanation for the major role played by Soviet women is the depletion of working-age males due to the wars and political purges of the last half century. At the

same time, rapid industrialization required large numbers of workers, including many newly trained technical personnel. This economic stimulus was reinforced by an ideological belief in the equality of women. Thus, the propaganda organs of the state were used to induce women into the schools, fields, and factories, and legislation prohibited employment discrimination on grounds of sex.

The lack of total control by the regime has been evident, particularly in the Moslem-dominated republics of Central Asia, where women still occupy a noticeably subordinate position. Elsewhere, however, the government efforts have met with impressive success. Women constitute a majority (52 per cent) of the labor force, with participation rates remaining high (near 80 per cent) even in the child-bearing and rearing ages. Thus, the Soviet Union has not yet had to face a problem of increasing concern in the United States—women who leave their jobs in their twenties and thirties and after a prolonged absence, during which their children are growing, would like to reenter the labor force. Also of little import in the U.S.S.R. has been the female demand for part-time rather than full-time employment. One wonders whether these problems will become more pronounced in the future, as the Soviet standard of living rises, relieving the pressure of economic necessity on female workers and making it possible for them to withdraw from the labor force while raising their families. Tapping female resources under these conditions may require more imaginative experimentation with educational and employment patterns—for example, adapting traditional recruitment practices, job training procedures, and work hours to meet the changing needs of women. This is a topic which might also be given greater attention in the United States, particularly in an era where long-run full employment is maintained.

Dodge's most valuable contribution comes in the latter half of his book, where he examines in detail the types of jobs held by women. Women constitute almost half of the industrial work force and over half of all "mental workers," a category which includes professional and scientific personnel. In this respect, the Soviet Union is probably utilizing its female resources better than any other country in the world, developing to a fine point the intellectual abilities and career motivation of its women. The United States might learn from this example.

Yet Dodge claims that women are not proportionately represented in positions of greater leadership and creativity; men still receive most graduate degrees and occupy most managerial and top government and party posts. (In fact, approximately 80 per cent of women workers are doing physical labor, the majority of these in agriculture, where women have historically predominated and continue to do so.) How can we explain this phenomenon? Dodge dismisses (perhaps too readily) the hypothesis that this is due to outright discrimination, although he does suggest that men benefit from the right contacts necessary for promotion to the top echelons. More crucial, he believes, is the handicap women suffer as a result of bearing the dual burden of family and job. This dilemma, apparently, has been resolved no better in the Soviet Union than in the United States, and in some ways less well. While the regime encourages female employment, it has been unwilling to divert

resources for an adequate number of nurseries or kindergartens to care for the young children of working mothers; only 10-20 per cent of children under age seven can be accommodated, and, unlike primary and higher education, this service is not free. Production of consumer durables has also been a low-priority item. Thus, domestic chores demand much of a women's time and energy, diminishing her desire for advanced training and her on-the-job productivity.

Dodge estimates that the lifetime work output of an average professional woman is 14 per cent less than that of a male, because of time lost through family obligations, health problems, and early retirement. He introduces several other measures of female productivity—by studying the sex distribution of memberships in scientific academies, of recipients of the Lenin prize for science or art, and of contributors to scholarly journals—and finds women clearly inferior here too. Some of these appear rather unconvincing as indices of productivity, and a bit of circular reasoning may be involved. Nevertheless, Dodge concludes that this lower female productivity explains the absence of women from the more responsible positions and justifies recent changes in educational admissions policies which favor males.

The book, enriched by extensive tables and graphs, provides an abundance (indeed, perhaps an overabundance) of data on female education and employment in the U.S.S.R. The careful reader may be disturbed by occasional unexplained statistical inconsistencies (as in Tables 21, 23, 24, 27, 29, and 90). Some of the early chapters are relatively limited in analytic content, but this is remedied toward the end. The discussion of the latter chapters is highly relevant to Western experience; at times one only wishes that Dodge had developed this international comparison a bit further.

Labor Market Institutions and Wages in the Lodging Industry. By JOHN P. HENDERSON. East Lansing: Michigan State University, Division of Research, Bureau of Business and Economic Research of Graduate School of Business Administration, 1965. Pp. ix, 227. \$6.50.

The nature of our economy has been changing rather significantly over the past decades. By the end of World War II we had clearly shifted from an agriculture-oriented economy to a manufacturing-oriented one. Only in recent years, however, have we begun to recognize the increasing importance of the service sector of the economy. The shift to service trades and industries is now occurring at a growing rate. But so far, not too many professional economists have considered this shift sufficiently significant to study and analyze the nature of these service industries. We are still putting forth a disproportionate amount of time and effort studying the manufacturing sector of our economy. And when individual industries come under close study, economists still seem to find more glamour in industries such as steel, autos, and rubber. The book here under review takes on the task of studying the labor market aspects of the lodging industry, one of the more important service industries in the United States.

John P. Henderson takes the standard steps necessary to report on and ana-

lyze the labor situation of an industry. He first analyzes the growth of service industries in the United States, and then goes on to describe the economic structure of the lodging industry. The industry incorporates a rather wide variety of economic units and activities: we have the small five-room hotel or motel with no payroll and the large luxury-type hotel with over 100 employees; there is the small road-side motel and the large town-motel with all the luxury services; there is the establishment furnishing lodging only and the one furnishing hotel rooms, plus restaurant, bar, entertainment, and banquet facilities.

The chapter on labor-market institutions is rather thin. References are made to obvious factors, such as unionization, the skill composition and the ethnic composition of the labor force, but none is treated in depth. However, in the next chapter, Henderson comes to grip with the basic problems of the wage structure, and here is the heart of the study. Henderson has done a creditable job of putting together and analyzing the rather scarce wage data available for the lodging industry. The structure is examined from the point of view of geographic differences among the various job classifications, and from the point of view of differences between the tip and the non-tip occupations. Again we have a verification of wide variations in wage structures among cities in different areas, and of differences between tip and non-tip classifications.

The remainder of the book discusses such topics as the minimum wage controversy in the industry, multi-employer bargaining, and the problems of federal jurisdiction over the industry. Some aspects of the topics discussed in the final third of the book appear as appendages to the problems of labor markets and wage structures discussed earlier.

Labor economists, and also the general reader who is interested in learning something about the labor market situation in other than steel or autos, will find this book a contribution to the field. Henderson writes well and presents his material in an orderly fashion. A complete reading of the book will give an understanding of, and a feel for, the lodging industry. While the reviewer would have preferred more emphasis upon labor market institutions and wage problems, this is a matter of taste. One has to admit that the study is a significant contribution in an area where we should encourage more work to be done.

MORRIS A. HOROWITZ

Northeastern University

Occupation and Pay in Great Britain, 1906-60. By GUY ROUTH. New York and Cambridge: Cambridge University Press, 1965. Pp. xi, 154. \$6.50.

After preparing a budget speech a weary Gladstone once wrote: "A load of figures has a suffocating effect upon the brain until they are well drilled and have taken their places." Fortunately for those interested in occupational wage differentials Professor Routh has drilled his figures admirably, and made them take their informative places. His book originated in a charge from the National Institute of Economic and Social Research to investigate "the changing economic fortunes of the principal 'Common interest groups' of which society is composed." It became primarily a presentation of "the changing size

of occupational classes and . . . their concomitant pay structure in Great Britain in the years 1906-1960." If we were fortunate enough to have a similar study of U.S. materials it would be readily recognizable as an NBER report—data having been extensively accumulated, effectively ordered, then altruistically made available to the profession for analysis. However a concluding chapter does offer a mixed bag of perceptive and contentious "interpretations."

Routh converts the established "social classes" of the Registrar-General's reports to "occupational classes," then reviews how numbers in these classes and many individual occupations, changed. His discussion of training time notes "surprisingly small differences" between formal education levels for unskilled and foremen, then emphasizes the penumbra of on-the-job training. No attempt is made to measure the advantage or consequence of such training—whether formal (*à la* Keat, Mincer, or Oi) or informal. Some international comparisons are made, particularly with the United States, leading to the suggestion that "technique and social advance" may override national boundaries to produce "similarities more striking than the differences."

In Chapter 2, on income and pay differentials, Routh finds a compression in the male income tax distribution from 1911 to 1958, but a widening distribution for females. Data added on weekly earnings by manual workers (in 1906, 1938, and 1960) help suggest that compression was achieved by 1938. They imply, however, that not much can be made of the income tax data for females until some adjustment is made for a possible increase in part-time workers. The bulk of this second chapter reviews trends in pay for individual occupations, and affords us a basis for more interesting inferences than can be drawn from net changes in the income distribution.

Chapter 3 offers a bewilderingly rich set of material on the time and circumstances under which the changes for the particular occupations took place. The familiar puzzle of a one-third cut in wage rates from 1921 to 1924, followed by a mere 5 per cent cut from 1924 to 1935 (despite unemployment rates of from 10 per cent to 20 per cent in every year), stares out of one table. Routh's new data accentuate the puzzle: despite the collapse of mining, textiles, and engineering, declines for many of these industries were minor. Actual rises during 1924-35 appear for some industries, for various occupations. Some reference to the extensive study by Janet Chapman would have been welcomed here.

In a concluding chapter on "interpretations" shrewd intuitions jostle explicit reservations about applying supply and demand concepts to the labor market. That the pay of the unskilled rose more than the skilled from 1914 to 1924 Routh finds to be "the reverse of what demand-supply relations would suggest"—apparently because the unemployment rate for the unskilled was greater than that for the skilled by 2 points in 1913 and by 23 points in 1921. Relating 1958-60 averages of vacancies to unemployment counts by occupation Routh finds that "great variations [appear] between occupations, which demand and supply theory postulates should be equalized by changes in relative pay." It is cheering to know that Marshall has not exorcized the ghost of Cliff Leslie, but depressing to find classical theory seen through fun house mir-

rors, demanding that the adjustment to excess supply (or demand) take place within a given time span. (Why should it require the complex impacts of the war rise and postwar catastrophe to cancel neatly? And even if so, why by 1924?) This section concludes that "in general the labour market does not operate in the way conceived by the theory of demand and supply; the price of labour may rise in the face of high unemployment; it may rise at similar pace for occupations showing contrasting demand-supply relationships," etc. Whose theory is being rebutted here is not clear. More important the author would have had a comparative advantage in utilizing the rich array of English data on vacancies, unemployment, and pay rates year by year and occupation by occupation in a model that even roughly, but systematically, allowed for the complex facts of the real and the (usual) theoretical world: job substitution and dilution, adjustments to excess supply completed at no constant rate and varying among industries, shifting demand schedules, the presence of unemployment insurance and employee savings, etc.

A concluding section, "An Explanatory Hypothesis," begins: "The outstanding characteristic of the national pay structure is the rigidity of its relationships," and goes on to note that despite fluctuations these "have the capacity to regain previous shapes, sometimes after lapses of many years." From this the writer eventually concludes that "attempts to formulate a national policy or manipulate a pay structure are misconceived if they are based on a belief in the effectiveness of price in the regulation of supply and demand. Bishops, judges and cabinet ministers have had their real pay drastically reduced in the last fifty years, yet there is still no shortage of candidates for those positions." It is, of course, a welcome pleasure to find the cut direct to both believers in free markets and in incomes policies or central wage fixing. But no blood will flow until, at the very least, it is established that Heath and Brown are equivalent say to Lloyd George, or Profumo to Morley. True, pay incentives probably never elicit a Pitt, or even a Perceval. But will they put a better bobby on the beat or a worker on the line? This is the more immediate concern of wage theory and wage policy. However one may differ on the "explanatory hypothesis" there can be no question that the extensive set of materials developed for this study will be of durable use to those concerned with the study of wage problems.

STANLEY LEBERGOTT

Wesleyan University

Wage-Structure in Theory and Practice. Edited by E. M. HUGH-JONES. Amsterdam: North-Holland, 1966. Pp. x, 242. \$7.00.

The editor, E. M. Hugh-Jones of the University of Keele, describes this book as an experiment. Economists in three countries—the United States, Great Britain, and France—were given the title and identical but short instructions and then left to write their essays as they pleased. This turned out to be an experiment not only in labor economics, but also in anthropology. Quite clearly, the U.S. and British contributors share roughly the same cultural heritage which makes them ask similar questions. The French contributors Jacques Lecaillon and Jean Marchal—whose main ideas, incidentally, had

been expressed previously in their monumental three-volume work, *La répartition du revenu national*—have quite different concerns. Mark W. Leiserson (U.S.) and J. R. Crossley (U.K.) inquire into the contribution which economic theory can make to our understanding of wage structures. If their answers differ, their questions and the way they go about answering them are quite similar and betray their common neoclassical Anglo-Saxon intellectual ancestry. The main interest of the French authors lies in identifying socioeconomic groupings among the wage recipients which a theory of distribution could operate with. These groupings are quite different in nature from—say—those an economist may establish by determining the degree of substitutability of one kind of labor for another. The French groupings are derived from such elements as social origin and legal distinctions. Most of them are broad categories such as “non-manual junior employees (clerical workers and civil servants).” Such wide groupings may be indispensable for many purposes, but not necessarily those which Leiserson and Crossley had in mind. The distinction between the general line of investigation of the French authors and that of the other two essays is the more remarkable as Marchal and Lecaillon are admirably well informed about published work on the theory of distribution in England and the United States. Other distinctions in the three essays, e.g. different weights given to such factors as a sense of social responsibility or class solidarity in wage determination, might also be of concern to a student of comparative economics.

For the “pure” economist, the main interest of the essays is likely to be in the authors’ attempts to answer the question of how much economic theory can help in explaining short-term changes in the wage structure. The authors seem to agree that in the long run competitive wage theory has a good deal to say in the analysis of changes in the wage structure. From this point on, however, the authors part company. Leiserson doubts whether conventional theory has much to offer for the explanation of short-term changes of the wage structure. The emphasis on equilibrium relationships in particular prevents “traditional theory” from throwing “much light on the dynamic process of wage setting” and the significance of changing institutions in the economy. No great progress, moreover, has been made in marrying institutional factors with the competitive hypotheses of conventional theory, however modified by assumptions of oligopolistic behavior. Indeed, some of the institutional regularities in an earlier period that appeared to contain the germs of possible generalizations such as the “key bargain” and the “wage pattern” have lost a good deal of their validity either in the light of later events or as a result of closer analysis. Dunlop’s “wage contours” have withstood the passage of time, but have remained so far a significant descriptive characteristic of wage changes in the United States without a theoretical foundation which would permit integrating the concept with other theoretical propositions. Crossley holds the opposite view. Market conditions have their impact on both wage rates and earnings in the short run. The empirical tests for this hypothesis are derived from the following reasoning: Since short-term supply curves of labor to a given industry or firm are less elastic than their long-term counterparts, a relative increase in the demand for labor will call forth an increase in supply

only if there is some increase in the relative wage. With the passage of time this increase may be reduced as long-term supply elasticities are higher. The competitive theory thus leads to two testable propositions: the wage structure changes more over the short run than over the long run and relative wage changes in the short run are positively correlated with relative employment changes. No such implications follow, according to Crossley, from nonmarket theories of the wage structure. Some empirical evidence for the two propositions is found in studies by Phelps Brown and Browne, Reddaway and others, but taken together the evidence can at best be described as suggestive. However, an examination of the evidence in support of the Phillips hypothesis modified by the adoption of three different wage measures (changes in rates, earnings, and wage drift) is taken to indicate that "market conditions in the short run . . . bear on the determination of the earnings level both through their effects on wage rates and on the gap between rates and earnings" (p. 223).

This is highly ingenious reasoning and I hate to question its validity. Yet, not only is the evidence cited by Crossley far from conclusive but also somewhat ambiguous. The main pillar of Crossley's reasoning needs additional support if the structure he wishes to build on it is to be stable. The degree of supply elasticity varies not only with the time span under consideration, but also with other factors including the level of unemployment in the economy, the area, the industry and occupation, as well as the facility of arranging or withdrawing overtime, etc. Changes in the qualifications required for a given job or in vacancy rates tolerated may take the place of wage variations and statistical data may conceal these phenomena. Lags in wage responses to changing demand conditions may also blur the picture. It is thus conceivable that, under certain conditions, supply elasticities may appear to be greater in the short run than in the long run or that relative wage increases or decreases in earnings follow relative employment changes with considerable delay. Crossley himself is disturbed by the high short-run elasticity of labor. The reason for this, he thinks is the reduction of uncertainty about the maintenance of a given wage through collective bargaining. This is unconvincing as far as wage rates are concerned, but may have some relevance for yearly earnings. Since, however, the impact of bargaining on uncertainty as regards lay-offs and short hours appears to be about the same in different industries under contract, it is difficult to see how collective bargaining could affect supply elasticities in a universe of unionized union-influenced firms.

I am not entirely convinced by the evidence regarding changes of the wage structure in the long run. It is conceivable that over long periods supply and demand schedules adjust to autonomous changes of the wage structure rather than the reverse so that the market may "justify" changes *post hoc* originating outside of the market. Far more intricate research methods will thus be required to test alternative explanations and to control for these and many other variables, before Crossley's tests can turn out more convincing results. Yet, his first-rate piece of analysis outlines a promising fresh line of research.

If the French study has been somewhat neglected in this review, this is not intended to be a reflection on its merits. Its most significant contributions,

however, are in areas closer related to sociology. The review of statistical material on French wage differentials, however, is meritorious, though somewhat dated.

Population; Welfare Programs; Consumer Economics

The Economics of Education—Proceedings of Conference Held by the International Economic Association. Edited by E. A. G. ROBINSON AND J. E. VAIZEY. New York: St. Martin's Press; London: Macmillan, 1966. Pp. xvii, 781. \$16.00.

This volume contains 24 papers on the economics of education presented at the International Economic Association's conference at Menthon St. Bernard in 1963.

The first section of the book is devoted to "General Problems of Education" and contains an interesting and useful article by F. Edding on education expenditures. Edding presents historical series of expenditure on education in 9 countries, extending in most cases to the pre-World War I period, along with a survey of expenditure in 20 countries over the decade of the 1950s.

The second section, entitled "Education and Economic Progress," contains the first generally available English translation of the Soviet academician S. G. Strumilin's celebrated 1925 paper on "The Economic Significance of National Education." Strumilin estimates the relationship between the level of skill, and age, years of employment, and years of education in a large sample of Leningrad metal workers. The measure of skill is based on official skill gradings and pre-World War I relative wages for each skill grade. The data provide an interesting insight on the skill formation effects of both on-the-job learning and education. A number of problems are not adequately treated in the paper; the chief ones are the failure to correct for the fact that both the duration and the quality of a year of schooling vary over time, and the difficulty of distinguishing between the effects of education on skill and the effects of other attributes, such as measured intelligence and family background, which are closely associated with the number of years of education. Further, in view of the fact that the results of Strumilin's work lead him to suggest very major changes in the amount of resources devoted to education, some recognition of the dependence of the earnings of various types of labor on the supply of each type of labor in the labor force would have been appropriate. Strumilin's estimates of the social rates of return on educational expenditures will be regarded by many contemporary economists as upward biased for they involve no discounting of future benefits, but given the circumstances one is tempted to view this aspect of the analysis as akin to the talking horse that is remarkable not so much for what it says, but because it talks at all.

It is a pleasant irony that the group of economists who set out from Chicago in the late 1950s on their exploratory voyage in the application of capital

concepts and market valuations to educational problems should now find that they had proceeded much of the way in the footsteps of a voyager who had embarked at Leningrad thirty years earlier; this coincidence no doubt constitutes one of the rare contributions to economic analysis originating jointly (if independently) with the Soviet Academy of Sciences and the University of Chicago department of economics.

M. C. Kaser's statistical study of patterns of educational evolution in the process of economic growth in the industrialized non-communist economies is an underanalyzed array of potentially very interesting data.

In Part III of the book, for some reason labeled "Demand and Supply," Raymond Lyons provides a good survey of the OECD's Mediterranean Regional Project, one of the most ambitious educational planning exercises yet attempted.

Part IV is devoted to "The Cost and Financing of Education." Mary Jean Bowman has provided a nicely argued piece on the nature of educational costs and some problems concerning dynamic aspects of training and education. Selma Mushkin raises the much ignored problem of the obsolescence of skills and offers a proposal for the re-education of adults on a mass basis which should attract considerable attention. John Vaizey's paper on expenditure criteria in the field of education surveys and finds considerable fault with a number of alternative approaches and concludes doubting "whether in the long run the concept of education as 'investment' will prove much of a guide on 'what ought to be spent on education'."

Part V on the "Balance Between Different Forms of Education" is seriously weakened by the failure of the authors to cope with the problem of establishing an operational or even conceptually interesting definition of balance. (As far as I could determine, the authors thought that balance was a good thing.) Michel Debeauvais' paper provides an interesting survey and some striking examples of statistical pitfalls in quantitative international comparisons of educational structure. The remaining papers in this section are devoted to problems of vocational and technical education.

In the concluding section on international aid to education H. M. Philips' paper provides a survey of the very sketchy available information on bilateral and multilateral educational assistance programs to the underdeveloped countries. H. B. Ripman's paper recounts the lessons learned by the International Bank's then recent entry into the field of financing educational projects. The absence of any consideration of the reverse flow of human capital from the poor to the rich countries is an unfortunate omission in this section.

The volume contains a number of articles directed to economic problems of education in particular countries: Nigeria, Turkey, Pakistan, the Soviet Union, and the OECD area. While these papers contain a sprinkling of insights they offer little material of general interest. At least three papers in the book (those by E. F. Denison, I. Svernilson, and F. H. Harbison) have been in print elsewhere for some time; their republication here hardly seems necessary.

The contents of this book are convincing evidence that the economics of education field offers both ample scope for continued controversy and a fertile

ground for further research. One of the many persistent differences of opinion among conference participants concerned the use of earnings as a measure of the economic effects of education, and the related problem of the foregone earnings component of educational costs. Much of the work presented at the conference, as well as more recent research, suggests that policy prescriptions based on the discounted future earnings approach differ in a rather consistent way from those generated by the various versions of the manpower requirements approach to resource allocation in education. An exploration of the sources of these differences might shed some light on the range of applicability of the various competing planning methods put forward at the conference.

A number of important problems were not seriously discussed at the conference. Chief among these omissions were the empirical investigation of the very imperfectly understood relation between education and earnings and the absence of any work on educational production functions. Further progress in these areas, and in the economics of education field generally, depends in large degree on careful empirical studies, probably at a fairly high level of disaggregation. Greater emphasis on this type of work at the expense of the wide geographical distribution of case studies would have done much to increase the usefulness of this volume.

The publication of this book by the International Economic Association can be thought of as a milestone in the recent development of the economics of education. With the exception of a very few papers, however, it adds very little to either our conceptual tools or our empirical understanding of the problems in this field. Taken as a whole, this eagerly (and longly) awaited volume will be a disappointment to most readers.

SAMUEL BOWLES

Harvard University

The Profitability of Investment in Education in Israel. By RUTH KLINOV-MALUL. Jerusalem: The Maurice Falk Institute for Economic Research in Israel, 1966. Pp. xiv, 109. (Published in English and Hebrew.)

This rather short book is primarily empirical, analyzing in great detail the profitability of investment in education in Israel. It provides useful results which can be compared to similar investigations in other countries (thus providing a basis for formulating hypotheses about education as a productive factor) and of course the conclusions will also be useful in guiding decisions for educational policy in Israel. Theoretical issues play two roles: as in any empirical investigation, they are used to indicate the relevant factual evidence; and they are important when the author considers the implication of economic growth upon education's profitability.

The earlier chapters present and analyze the data used to estimate the returns to education. The present value rather than the internal rate of return technique is used throughout, and values (at age 21) of various income streams are provided using alternative discount rates of 6, 8, and 10 per cent. Later chapters consider the cost of education, both direct expenditures and income foregone. The very surprising conclusion is that, after completion of primary education, there is no clear-cut evidence that investments in educa-

tion are profitable, when the opportunity cost of money is 8 per cent or greater. This is true whether social or private returns are considered although social returns appear to be higher, primarily because the loss resulting from increased income taxes more than offsets the gain realized by the subsidized education (tuition less than total cost).

The brevity and the level of the exposition make the book difficult to read. The text consists of only 76 pages and has been gleaned to the bare essentials. Introductory arguments are often sketchy and the reader should be familiar with the more common statistical and theoretical problems of evaluating education's costs and returns. Owing to its brevity, the text contains many statements of the "if-then" variety which are not supported and tax the reader's ability to discern their accuracy. In general they are accurate and support the impression that the author is an extremely competent analyst.

Several short appendices follow the text. They indicate the wide range of phenomena considered in the study as well as suggest important issues to be considered. The appendices are particularly interesting for it is here that some of the rigor and care that characterize the text are relaxed and the author allows herself freedom to speculate.

The description of the empirical techniques deserves praise. The methods are obvious to the reader and one feels that, given the basic data, the results could be recomputed. This is certainly superior to most presentations in which the underlying "adjustments and corrections" are swept under the rug. When an arbitrary decision is made, the reader is informed. However, the numerous assumptions necessary to reconcile data from several sources and to use cross-sectional estimates of age-earnings profiles lead to the authors' admonition against reaching unwarranted conclusions from the results. Indeed she suggests that the principal role of the study is "... to systematize thought in an important field" and to "... serve as a basis for further research." Here, it seems that she worries too much. It is likely that the evidence provided in this book is superior to any other concerning the profitability of educational investments in Israel. Surely many simplifying and perhaps heroic assumptions were required, but complex problems always do! To ignore conclusions based upon such assumptions begs the whole point of the alternative cost theory. For until other data are available what alternatives exist?

The analysis is couched in terms of a three-variable production process in which education complements other factors and tangible capital substitutes for unskilled labor. Thus, when considering prospects for future profitability of education, Miss Klinov-Malul concludes that, if the impetus for economic growth comes from education, its profitability will decline, but if capital accumulation provides the impetus, it will increase. It is also argued that, if growth occurs through technical change that is neutral between education and other factors, then the profitability of educational investments will increase. This proposition appears in both the introductory and concluding sections, but the reasons for such a conclusion are illusive. The argument is simply that neutral growth will increase the wages of skilled and unskilled laborers by the same proportion. Since the return to education is the difference between the skilled and unskilled wages, the return to skill acquisition also increases equi-proportionately. But what about costs? If the marginal products of all factors

increase in proportion to the technical change then costs must have increased in proportion to returns. Investments that were profitable before the change will be more profitable afterwards but marginal investments will remain marginal and those that involved losses will involve even greater losses.

If the technical change increases all wages equiproportionately but does not involve corresponding increase in the marginal products of other factors, then education will become more profitable but not so much as would appear at first blush. The return would obviously increase but so would cost. Education is labor intensive, the two most important elements of cost being income foregone and instructional salaries, each of which will increase in proportion to the return. Too, prices of other factors will increase since labor is used in their production. Thus the net gain in profitability is less than normally assumed.

The book summarizes a difficult piece of research performed by a competent analyst. Most of the tools are not new yet they are not misused. The conclusions are interesting and add significantly to our growing body of knowledge concerning education as an investment alternative and as a factor of production. I would certainly recommend it to anyone formulating educational policy in Israel as well as to the serious student of human capital. The casual reader can do better elsewhere.

Secrecy and the Arms Race. By MARTIN C. MCGUIRE. Cambridge: Harvard University Press, 1965. Pp. x, 249. \$5.95.

As the subtitle indicates, this book elaborates "a theory of the accumulation of strategic weapons and how secrecy affects it." While the debt to previous authors, in particular Lewis F. Richardson, Kenneth Boulding, and Thomas Schelling is clear, the author has succeeded not only in synthesizing their approaches but also in developing new and important aspects of the theory of arms races where an arms race means here an interacting sequence of decisions by two nations to acquire missiles. (McGuire considers only one type of weapon, a missile.)

Perhaps the most important contribution of this book to the scarce literature on the subject of arms races is its use of explicit economic concepts. Conversely, from the viewpoint of economics the book indicates a new field ripe for economic reasoning. The problem of economic allocation considered by McGuire is that of allocating a given (scarce) level of national wealth between the competing ends of missiles, which have no intrinsic value, and alternative uses of national wealth, which do have an intrinsic value. Why a nation should then buy missiles or, equivalently, why missiles should have some indirect value, is seen on the basis of a second problem of economic allocation. The second problem is that of allocating a given (scarce) number of missiles among the competing ends of firing missiles against enemy missiles (a *counterforce* operation), firing the missiles at enemy cities (a *countervalue* opera-

tion), and not firing the missiles (a *holding* operation). McGuire assumes that the solution to this second problem is one for which the attacker fires a certain proportion of his missiles (but not all of them) in a counterforce operation against his opponents' (the defender's) missiles. The number of missiles remaining for the defender after this attack is then a random variate depending on the number, yield, and accuracy of the attacking missiles and the number and vulnerability of the defending missiles. The minimum number of defending missiles that would, with some specified degree of confidence, survive an initial attack by the other side is then the retaliatory capability, a concept which plays a central role in McGuire's analysis.

McGuire considers only two countries and assumes that the national utility functions, summarizing the "tastes" of the problem, depend on the retaliatory capabilities of both sides and the alternative uses of national wealth. If the two countries are X and Y , then the national utility function for X depends on the retaliatory capability of X (assuming Y strikes first), the retaliatory capability of Y (assuming X strikes first), and the alternative uses of national wealth for X (other than for missiles). An increasing retaliatory capability for X increases utility (but at a decreasing rate) since it would, if known by Y , deter Y both from attacking initially and from subsequently attacking X cities for fear of retaliation. To take an extreme case, if X had no retaliatory capability (i.e., Y had a disarming first strike capability), then there would be a great incentive for Y to attack since after a Y attack X would have little choice but to capitulate in the presence of the remaining Y missiles. Thus the desire of X for security leads to the dependence of its utility function on its own retaliatory capability. On the other hand, to the extent that X desires power its utility function depends on its opponent's retaliatory capability, where an increasing retaliatory capability for Y decreases utility (but at an increasing rate) since such a capability could be used for retaliation following an initial attack by X . Finally the utility function depends on alternative uses of national wealth, where increasing alternative uses increase utility (but at a decreasing rate). To simplify, McGuire assumes that the utility function is independent and additive.

Having specified "tastes" the next step is of course to specify "technology." If the missiles are thought of as "costs" (representing a diversion of national wealth) and the retaliatory capabilities are thought of as "benefits" (each advancing the interests of one side, but retarding those of another) then the technology is summarized by cost schedules, showing how much any particular level of retaliatory capability would subtract from national wealth. Combining the "tastes" summarized by national utility functions with the "technology" summarized by missile cost schedules, McGuire obtains an optimum at the point where:

$$\frac{MU \text{ of own retaliatory capability}}{MC \text{ of own retaliatory capability}} + \frac{MU \text{ of enemy retaliatory capability}}{MC \text{ of enemy retaliatory capability}} = MU \text{ of money}$$

Now focussing attention on the interaction process inherent in the arms race, since there are two opponents with conflicting interests (only partially conflicting, i.e., nonzero sum since alternative uses of national wealth enter the utility functions), the arms race leads to a theoretical structure similar to that of duopoly. The various solutions to the duopoly problem have been likened by McGuire to various outcomes in the arms race. For example the naive (Cournot) solution corresponds to an arms race toward the intersection of reaction curves (but not necessarily an "unrelenting" arms race as McGuire states); the contract curve (Pareto) solution corresponds to an arms control agreement; and the leader-follower (Stackelberg) solution corresponds to unilateral disarmament. These analogies might be useful pedagogically in motivating duopoly theory.

The second important contribution of this book to the study of arms races is its discussion of the importance and influence of secrecy. From the viewpoint of economics this book indicates the importance of studying uncertainty in the context of duopoly, where uncertainty is perhaps most important because it can be varied, at a cost, by the actions of the rival firms, for whom secrecy, intelligence operations, and the establishment of open or closed societies are almost as pervasive and important as they are for rival nations.

McGuire treats two types of imperfect information: first, that which can be represented by a probability distribution ("risk" to an economist), for example imperfect information concerning the number, yield, accuracy, and vulnerability of missiles, and second, that which cannot be represented by a probability distribution ("uncertainty" to an economist), for example imperfect information concerning target location, especially for mobile missiles such as Polaris, and enemy intentions. McGuire shows that the effects of imperfect information are manifold, affecting cost curves (as shown via numerical simulations), utility levels, equilibrium points, and hence the rate and direction of the arms race and even the basic character of the rivalry between the two nations. An interesting result is the social value of secrecy resulting from the possibility that it might promote deterrence relative to attack and hence stabilize against the outbreak of war. Thus arms control agreements which partly destroy secrecy might increase the probability of war. McGuire gives the example of an agreement to limit numbers of missiles with no limitation on war-head technology, which would eventually allow both sides to achieve a disarming first strike capability. Another example would be general disarmament, where both sides could, by acquiring a few weapons, achieve dominance.

As has been indicated, this study has made important contributions in elaborating an approach to the study of arms races and in suggesting the importance of imperfect information. Unfortunately, however, the specific results of this approach appear to be weak or obvious. For example: "... our theory illustrates ... the fruitlessness of a search for absolutes in security" (p. 45); "... one central message of this study ... is embraced by the adage 'Know thy enemy'" (p. 46); "... not all arms control schemes merit approval" (p. 26); "... it can pay one to bribe secrets out of a rival." There are also some apparent inconsistencies: "... the theory ... indicates no clear-cut line between

quality and quantities of weapons" (p. 45) vs. ". . . The optimum allocation between quantity and quality depends on the magnitude of the missile force . . . [and] on the size and character of the opponent's forces" (p. 105). We may hope that sharper and more interesting conclusions will come from future studies that are either more specific (e.g., using specific functions instead of functional forms) or more general (e.g., allowing for more than one weapon, leading to tradeoffs between weapons and allowing for more than two countries, leading to the possibility of coalition formation).

To an economist the three interesting aspects of this book, as indicated above, are the opening up of a new field for economic reasoning, the possible use of arms races as a way of illustrating duopoly theory, and the importance of extending the theory of duopoly to allow for imperfect information and its variation as a specific policy instrument.

NOTES

The Asia Foundation has again made it possible for the American Economic Association to make a limited number of travel grants to individuals from certain Asian countries who (1) are enrolled at an educational institution in the United States and (2) plan to return to their native country after completing their education. Application forms are available from the American Economic Association, 629 Noyes Street, Evanston, Illinois, 60201.

NEW JOURNALS

The *Journal of Economic Issues*, a new quarterly co-sponsored by the Association for Evolutionary Economics and the University of Texas, will begin publication in the spring of 1967. This *Journal* will be broadly concerned with major issues of public policy, of economic methodology, and of understanding the processes and problems of economic change. To join the Association and receive its *Journal* write to Professor Ben B. Seligman, 125 Draper Hall, University of Massachusetts, Amherst, Mass. 01003. Annual dues are \$5.00. Communications about library subscriptions (\$6.00 per year, payable to the University of Texas), should be sent to Professor Forest G. Hill, Editor, *Journal of Economic Issues*, University of Texas, Austin, Texas 78712.

A new journal, *The Review of Income and Wealth*, began publication with its March, 1966 issue. The journal is published by the Yale University Press for the International Association for Research in Income and Wealth under the editorship of Mr. Odd Aukrust, Central Bureau of Statistics, Dronningens Gate 16, Oslo, Norway. Communications on subscriptions and other business matters should be addressed to the International Association for Research in Income and Wealth, Box 2020, Yale Station, New Haven, Conn. 06520, U.S.A.

The *Statistical Reporter*, issued by the Bureau of the Budget, reports monthly on current developments in federal statistics. Current developments include descriptions of statistical surveys and programs, major publications, and important organizational changes. Occasional articles appear on international, State, and local statistical activities. The *Statistical Reporter* is oriented primarily to federal personnel working on statistical programs and has been prepared for distribution within the government since 1939. Because of a widening use of and interest in federal statistics, it is now available to the general public. Subscriptions, at \$2.25 per year, are available from the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402.

Announcements

The Institute of Advanced Projects of the East-West Center in Honolulu, Hawaii, each year invites several groups of eminent scholars and specialists to spend some months at the Center in research and writing, under its Senior Specialists Program. In addition to this program the Institute sponsors the Research Translations Program, which endeavors to increase the flow of translations, particularly from Asian languages into English, in the areas of particular interest to the Center; and the International Development Fellowships Program, which supports advanced study and research in the application of the social sciences to the complex problems of contemporary economic, social, and political change in the Asian and Pacific areas. For more information about these programs, write to the Director, Institute of Advanced Projects, East-West Center, Honolulu, Hawaii 96822.

The Survey Research Center of the University of Michigan will hold its twentieth Summer Institute in Survey Research Techniques in 1967. There will be two four-week sessions, the first from June 28 to July 21 and the second from July 24 to August 18. The Institute is designed for men and women engaged in business and governmental research and other statistical work and for graduate students and university teachers interested in quantitative research in the social sciences. Detailed information may be obtained from the Survey Research Center, University of Michigan, P.O. Box 1248, Ann Arbor, Michigan 48106.

Authors of papers for possible inclusion in the Medical Care Section Program of the October 1967 annual meeting of the American Public Health Association should write to Dr. Donald C. Riedel, Yale University School of Medicine, 60 College Street, New Haven, Connecticut 06504, to obtain standard abstract forms. Two types of papers will be considered: research reports and descriptions of programs or demonstrations. The deadline for submitting abstracts is April 14, 1967. Papers will be selected by early June.

A conference on the centenary of Alexander Bryan Johnson's death will be held in Utica, N.Y., on September 8-9, 1967, under the sponsorship of Hamilton College and the Munson-Williams-Proctor Institute. Besides giving recognition to the importance of Johnson's *Treatise on Language* of 1836, attention will be paid to his close affiliations with John Adams and John Quincy Adams, his works on economic theory, banking, and on American political problems ranging from the Jacksonian era through the Civil War. Anyone having letters or documents relating to A. B. Johnson, or otherwise able to contribute to the conference, is asked to communicate with Professor Charles L. Todd, Hamilton College, Clinton, N.Y. 13323.

Professor Hugh S. Norton, department of economics, University of South Carolina, Columbia, South Carolina, has under way a book dealing with the role of the professional economist as advisor in the federal government since 1920. Professor Norton would appreciate hearing from economists who served in the early period (1920-1940), or who know others who served, with a brief statement as to the character of the service. Records of these years are sketchy, at best, and it is desirable to make the record as complete as possible.

Deaths

Eugene E. Agger, professor emeritus, Rutgers—The State University.

Wesley C. Ballaine, director, Bureau of Business and Economic Research, University of Oregon, September 25, 1966.

Vernon C. Fowke, Britnell professor of economics, University of Saskatchewan, Saskatoon.

J. Edward Hedges, April 27, 1966.

Royal E. Montgomery, professor emeritus, Cornell University, June 13, 1966.

T. Bruce Robb, October 30, 1966.

Retirements

Lester S. Kellogg, corporate economist, Deere & Company, Moline, Illinois.

Margaret Linnan, associate professor of business administration, Washington State University.

Theresa Wolfson, professor of economics, Brooklyn College, February 1967.

Charles F. Ziebarth, associate professor, School of Business Administration, University of Oregon.

Visiting Foreign Scholars

A. W. Coats, University of Nottingham: visiting professor of economics, Stanford University, autumn 1967.

P. Sargent Florence, University of Birmingham: visiting distinguished professor of economics, University of Rhode Island, spring semester.

Francisco Forte, University of Turin: visiting professor of economics, University of Virginia, spring 1967.

Herbert S. Frankel, University of Oxford: visiting professor of economics, University of Virginia, spring 1967.

Willem Grader, Nederlands Opleidings Instituut Voor Het Buitenland, The Netherlands: European exchange professor, University of Oregon, 1966-67.

Michael C. Kaser, Oxford University: visiting professor of economics, University of Michigan, 1966-67.

Alexander M. Kerr, University of Western Australia, Nedlands: visiting professor of economics, University of Texas, spring 1967.

Peter Mathias, University of Cambridge: visiting professor, University of California, Berkeley, spring and summer 1967.

Vladimir Pertot, University of Ljubljana, Yugoslavia: visiting professor of economics, Stanford University, February-April 1967.

Graham L. Reid, University of Glasgow: visiting associate professor, School of Labor and Industrial Relations, Michigan State University, January-June 1967.

Norman Sun, International Christian University, Tokyo: visiting professor of economics, Temple University, 1966-67.

Eugene Zaleski, Centre National de la Recherche Scientifique, Paris: visiting professor of economics, University of Virginia, spring 1967.

Promotions

Booth, E. J. R.: professor of economics, University of Connecticut.

H. E. Bronson: assistant professor of economics, University of Saskatchewan, Saskatoon.

Kalman J. Cohen: professor of economics and industrial administration, Graduate School of Industrial Administration, Carnegie Institute of Technology.

Davd G. Davies: professor of economics and business administration, Duke University.

Ragaei El Mallakh: professor, University of Colorado.

Glenn W. Fisher: professor, Institute of Government and Public Affairs, University of Illinois, Urbana.

M. Blanche Fitzpatrick: assistant professor of economics, Boston University.

William P. Glade: professor of business, University of Wisconsin.

Richard L. Gordon: associate professor, College of Earth and Mineral Sciences, Pennsylvania State University.

M. F. Hassan: associate professor of economics, University of Miami.

Karel Holbik: professor of economics, Boston University.

Samuel Hollander: associate professor of political economy, University of Toronto.

John J. Hughes: professor of economics, Boston University.

William Iulo: economist and professor, College of Economics and Business, Washington State University.

Paul Jonas: associate professor of economics, Brooklyn College.

Kathleen M. Langley: association professor of economics, Boston University.

John H. Lorant: assistant professor of economics, Douglass College.

Michael C. Lovell: professor of economics, Graduate School of Industrial Administration, Carnegie Institute of Technology.

Chris J. Luneski: associate professor, School of Business Administration, University of Oregon.

Sarah Montgomery. associate professor of economics, Mount Holyoke College.

Thomas H. Naylor: associate professor, department of economics and business administration, Duke University.

Charles F. Phillips, Jr.: professor of economics, Washington and Lee University.

Leonard A. Rapping: associate professor of economics, Graduate School of Industrial Administration, Carnegie Institute of Technology.

Stuart U. Rich: professor, School of Business Administration, University of Oregon.

Ronald D. Schoesler: assistant professor, College of Economics and Business, Washington State University.

Norman R. Smith: associate professor, School of Business Administration, University of Oregon.

Paul N. Taylor: professor of economics, University of Connecticut.

Arthur S. Thomas: associate professor, School of Business Administration, University of Oregon.

Jaroslav Vanek: professor of economics, Cornell University.

Ruth E. Warnke: associate professor, College of Economics and Business, Washington State University.

Andrew M. Watson: associate professor, department of political economy, University of Toronto.

Imanuel Wexler: associate professor of economics, University of Connecticut.

William P. Yohe: professor, department of economics and business administration, Duke University.

Administrative Appointments

William F. Beazer: acting chairman, department of economics, University of Virginia, 1966-67.

Charles E. Bishop, North Carolina State University: executive director, President's National Advisory Commission on Rural Poverty, Washington, D.C.

Merwyn G. Bridenstine: acting dean, College of Business Administration, University of Arkansas.

Martin Bronfenbrenner: head, department of economics, Graduate School of Industrial Administration, Carnegie Institute of Technology. On leave at the Center for Advanced Studies in the Behavioral Sciences, Stanford, California, 1966-67.

Oscar S. Dooley: acting chairman, department of economics, Temple University.

Robert W. French: acting dean, College of Business Administration, University of Illinois, Chicago.

Virginia L. Galbraith: chairman and professor, department of economics and sociology, Mount Holyoke College.

Meredith B. Givens: chief, Manpower and Human Resources Branch, Education and Planning Service, Office of Technical Cooperation and Research, AID.

Roy J. Hensley: chairman, department of economics, University of Miami.

John Kane: head, department of economics, University of Arkansas.

R. W. Kautz: acting head, department of economics and political science, University of Saskatchewan, Saskatoon.

Juanita M. Kreps: director of undergraduate studies, Duke University.

Robert A. Lynn: resident director, Whiteman Air Force Base Graduate Program in Business, University of Missouri.

Henry Ponder, Fort Valley State College: dean, Alabama A. and M. College.

Alan L. Ritter: assistant dean, School of Business Administration, Emory University.

Charles L. Shaffer: assistant to the dean, School of Business Administration, The American University.

Robert Solomon: director, Division of International Finance, Federal Reserve System.

Rolf A. Weil: president, Roosevelt University.

Clifton R. Wharton, Jr.: acting executive director, Agricultural Development Council, Inc., New York.

Appointments

Robert T. Aubey: assistant professor of business, University of Wisconsin.

G. Leland Bach, Carnegie Institute of Technology: Frank E. Buck Professor of Economics and Public Policy, Graduate School of Business, Stanford University.

David S. Ball: instructor in economics, North Carolina State University.

Lee S. Balliet, University of Texas: instructor in economics, University of Wisconsin.

Jack Baranson, Indiana University: economist, International Bank of Reconstruction and Development.

W. Scott Bauma: associate professor, School of Business Administration, University of Oregon.

R. G. Beck: assistant professor of economics, University of Saskatchewan, Saskatoon.

John Bell, University of Illinois, visiting professor of economics, California State College, Los Angeles.

John D. Bossons, Carnegie Institute of Technology: associate professor of political economy, University of Toronto.

Thomas F. Brady: lecturer in economics, Queens College, City University of New York.

Louis F. Buckley, Bureau of Employment Security, U.S. Department of Labor: associate professor of industrial relations, Loyola University.

Edward G. Cale: visiting professor of economics, University of Oregon.

Garrey E. Carruthers: research associate, department of economics, Iowa State University.

John J. Casson, Jr., Port of New York Authority: economist, The United Corporation.

Nai-Ruenn Chen, University of California, Berkeley: assistant professor of economics, Cornell University.

A. P. Clark: assistant professor of management and business law, University of Florida.

Donald P. Cole: instructor in economics, Drew University.

Eaton H. Conant: associate professor, School of Business Administration, University of Oregon.

John P. Cooke: assistant professor of economics, University of Miami.

James Crotty: lecturer in economics, State University of New York, Buffalo.

Clarence T. Cuthbert, U.S. Army (retired): instructor in economics, Temple University.

Fred Dickey: instructor in economics, State University of New York, Albany.

P. C. Dooley: assistant professor economics, University of Saskatchewan, Saskatoon.

Herbert C. Driver: research associate, department of economics, Iowa State University.

Sheila B. Eastman, York University: assistant professor of economics, University of Toronto.

Peter Eilbott: assistant professor of economics, Queens College, City University of New York.

W. Bruce Erickson, Bowling Green State University: assistant professor of management, production and transportation, University of Minnesota.

Donald R. Escarraz, University of Florida: associate professor of economics, University of Georgia.

Louis M. Falkson: assistant professor, College of Engineering, Cornell University, 1966-67.

Yuan-Sheng Fan: coordinator, Committee of Economics, Republic of China and executive director, Chinese Society for Electronic Data Processing, Taiwan.

Rawle Farley, Ministry of Planning and Development, Libya: professor of economics, State University of New York, Brockport.

Irving M. Field: assistant professor, College of Economics and Business, Washington State University.

Paul Fischer: lecturer in economics, Queens College, City University of New York.

Heywood Fleisig: assistant professor of economics, Cornell University.

Charles F. Framingham: research associate, department of economics, Iowa State University.

Raymond S. Franklin: lecturer in economics, Queens College, City University of New York.

Barry L. Friedman: assistant professor of economics, North Carolina State University.

Walter Galenson, Social Science Research Council Committee on the Economy of China: visiting professor, Industrial and Labor Relations School, Cornell University, 1966-67.

Alex Gardezky: instructor in economics, Temple University.

Jack E. Gelfand, Temple University: professor of economics, State University of New York, Albany.

Alfred Gobar: assistant professor of finance, California State College, Los Angeles.

Christopher Green: assistant professor of economics, North Carolina State University.

Abdessatar Grissa: assistant professor of economics, University of Connecticut.

Wahidul Haque, University of Alberta: associate professor of political economy, University of Toronto.

C. Obert Henderson: associate professor, College of Economics and Business, Washington State University.

John B. Henderson: international economist, Joint Economic Committee, U.S. Congress.

Roy J. Hensley: professor of economics, University of Miami.

David F. Holmes: research associate, department of economics, Iowa State University.

William Holmes: assistant professor of economics, Temple University.

George Ignatin: instructor in economics, Trinity University.

Madelyn L. Kafoglis: interim associate professor of finance, University of Florida.

Kye Chil Kim: assistant professor of economics, University of Connecticut.

Sun Kee Kim: assistant professor of economics, California State College, Los Angeles.

Sungwoo Kim: lecturer in economics, State University of New York, Buffalo.

Alan P. Kleinman: research associate, department of economics, Iowa State University.

Andrew I. Kohen: instructor in economics, University of Connecticut.

Marshall Kolin: assistant professor of economics, Rutgers—The State University.

Serge-Christophe Kolm: associate professor of economics, Stanford University, winter 1967.

Karen Koziara: assistant professor, School of Business Administration, Temple University.

Robert E. Krainer: assistant professor of business, University of Wisconsin.

Udo E. Kramer, Copley International Corporation, La Jolla, California: associate professor of international business and marketing, School of Business Administration, The American University.

Judith R. Lave: instructor in economics, Graduate School of Industrial Administration, Carnegie Institute of Technology.

K. Laycock: instructor in economics, University of Saskatchewan, Saskatoon.

Guo-I Lee: member, Planning Commission for Recovery of Mainland China, Taiwan.

Pong S. Lee: assistant professor of economics, State University of New York, Albany.

Malcolm Liggett: assistant professor of economics, California State College, Los Angeles.

Jung-Chao Liu, McGill University: economist, International Bank for Reconstruction and Development.

Louis F. Lombardi: principal economist, Division of Water Resources, Department of Conservation and Economic Development, Virginia.

Milton D. Lower: lecturer in economics, University of Maryland.

Yao-Chi Lu: research associate, department of economics, Iowa State University.

Denis I. Lucey: research associate, department of economics, Iowa State University.

James A. MacMillan: research associate, department of economics, Iowa State University.

Shah Mahmoud: instructor in economics, Rutgers—The State University.

William F. Massy: visiting professor of marketing, Graduate School of Industrial Administration, Carnegie Institute of Technology.

Franklin McCarthy: assistant professor, School of Business Administration, University of Oregon.

Warren W. Menke: research associate, Bureau of Economic and Business Research, University of Florida.

Richard U. Miller: assistant professor of business, University of Wisconsin.

Raymond Nimeh: assistant professor of economics, University of Saskatchewan, Saskatoon.

Bernard Okun, Queens College, City University of New York: associate professor of economics, Brooklyn College.

R. Rodney Pakonen: instructor, College of Economics and Business, Washington State University.

Ransford W. Palmer, Central Connecticut State College: assistant professor of economics, The Catholic University of America.

Robert Pettengill: professor of economics, State University of New York, Albany.

Joyce Pickersgill: assistant professor of economics, California State College, Fullerton.

Arnold Raphaelson, University of Maine: associate professor of economics, Temple University.

Terry E. Rogers: lecturer in economics, Queens College, City University of New York.

John Rowntree: assistant professor of economics, State University of New York, Buffalo.

Ugo Sacchetti, International Monetary Fund: adviser, economics department, International Bank for Reconstruction.

A. E. Safarian, University of Saskatchewan: professor of economics, University of Toronto.

H. Arthur Sandman: instructor in economics, North Carolina State University.

Gerald W. Sazama: assistant professor of economics, University of Connecticut.

Gerald E. Schluter: research associate, department of economics, Iowa State University.

Jugal K. Sharma: assistant professor of economics, University of Calgary, Canada.

Jerry J. Shipley: lecturer in economics, University of Maryland.

Allen Sinai: assistant professor of economics, University of Illinois.

Russell J. Singer: instructor in economics, Rutgers—The State University.

Rafael A. Sison: staff economist, Council of Governments, Metropolitan Washington, D.C.

Lawrence B. Smith: assistant professor of economics, University of Toronto.

Emil G. Spitzer: senior economic affairs officer, United Nations, New York.

William M. Sukel: instructor in business administration, Emory University.

Lloyd A. Swanson: assistant professor, College of Economics and Business, Washington State University.

William K. Tabb: assistant professor of economics, University of Connecticut.

Sheila Tschinkel: lecturer in economics, University of Connecticut.

Theodore Tsukaharo: assistant professor of economics, California State College, Los Angeles.

Bernard D. Tuchman: lecturer in economics, Queens College, City University of New York.

George M. von Furstenberg: assistant professor of economics, Cornell University.

Theodore Voyadjis: assistant professor of economics, California State College, Fullerton.

Hsin Fu Wang: appointment in economics, University of Portland.

Pearl R. Willing: staff economist, U.S. Army Corps of Engineers North Atlantic Division.

Robert J. Willis: assistant professor of economics, Wesleyan University.

John Parke Young, Division of International Finance, Department of State: visiting professor of economics, Claremont Graduate School, 1966-67.

Nail C. Yucel: instructor, College of Economics and Business, Washington State University.

Dister K. Zschock: lecturer in economics, State University of New York, Stony Brook.

Leaves for Special Appointments

David A. Baerncopf, University of Oregon: associate professor, Amos Tuck School of Business Administration, Dartmouth College, spring 1967.

C. Phillip Baumel, Iowa State University: chief-of-party, Iowa-Peru project on agrarian reform and economic development, AID, 1966-68.

Philip M. Carroll, Colorado State University: resident director, Ohio State University Graduate Center, Ellsworth Air Force Base, South Dakota, 1966-67.

Alpha C. Chiang, University of Connecticut: visiting professor, Cornell University, 1966-67.

Benjamin Cohen, Harvard University: Office of Program Coordination, AID, 1966-67.

Louis De Alessi, Duke University: appointment at Institute of Defense Analyses.

F. Trenery Dolbear, Jr., Carnegie Institute of Technology: visiting assistant professor of economics, Stanford University, 1966-67.

William T. Esterbrook, University of Toronto: principal adviser Ministry of Economic Planning, Government of Tanzania, Dar Es Salaam.

Reed R. Hansen, Washington State University: acting chief, Personal Taxation Staff, U.S. Treasury, 1966-67.

Sidney Klein, Rutgers—The State University: visiting professor of mathematics and economics, University of Hong Kong and research associate, Institute of Modern Asian Studies, University of Hong Kong, 1966-67.

Walter Krause University of Iowa: chief, survey team to Colombia, Inter-American Committee on Alliance for Progress, spring 1966.

Ta-Chung Liu, Cornell University: Jacob Ziskind visiting professor of economics, Brandeis University, 1966-67.

Arthur T. Mosher, Agricultural Development Council: appointment to department of agricultural economics, University of Minnesota, 1966-67.

David M. Nowlan, University of Toronto: economic adviser, Ministry of Economic Affairs and Development, Dar Es Salaam, Tanzania.

Erik Thorbecke, Iowa State University: head, Sector and Market Analysis Section, AID, 1966-67.

H. John Thorkelson, University of Connecticut: visiting associate professor, University of Saskatchewan, Regina, 1966-67.

Stephen G. Triantis, University of Toronto: director, Harvard project in Greece on economic planning.

J. William Uhrig, Iowa State University: director of economic research, Farmers Grain Dealers' Association, Iowa.

Pan A. Yotopoulos, University of Wisconsin: visiting associate professor of economics and acting director, Economic Research Center, University of Hawaii, 1967.

Resignations

Sonia Gold, Carnegie Institute of Technology, June 30, 1966.

Wladimir Naleszkiewicz, University of Notre Dame.

Norton C. Seeber, Carnegie Institute of Technology, June 30, 1966.

VACANCIES AND APPLICATIONS

The Association is glad to render service to applicants who wish to make known their availability for positions in the field of economics and to administrative officers of colleges and universities and to others who are seeking to fill vacancies

The officers of the Association take no responsibility for making a selection among the applicants or following up the results. The Secretary's office will merely afford a central point for clearing inquiries; and the *Review* will publish in this section a brief description of vacancies announced and of applications submitted (with necessary editorial changes). Since the Association has no other way of knowing whether or not this section is performing a real service, the Secretary would appreciate receiving notification of appointments made as a result of these announcements. It is optional with those submitting such announcements to publish name and address or to use a key number. Deadlines for the four issues of the *Review* are February 1, May 1, August 1, and November 1.

Communications should be addressed to: The Secretary, American Economic Association, 629 Noyes Street, Evanston, Illinois 60201.

Vacancies

Labor economists and/or statisticians: The measurement of the economic damages suffered by those who are wrongfully injured or killed is a new area for the application of economic and statistical knowledge and research techniques. This field has been pioneered successfully and Associated Appraisers of Earning Capacity is now providing this service to attorneys on a nationwide basis. Those in it appraise the losses and are required to testify as an expert in court trials and must withstand hostile cross-examination. It is one of the highest-paid forms of work in the profession and it is possible to engage in it as a part-time activity. Requirements: (1) minimum status of associate professor; (2) experience in research in collective bargaining agreements and fringe benefit programs; (3) location in or near a major metropolitan area. Openings now available in following areas: Boston, Philadelphia, Pittsburgh, Chicago, Minneapolis, St. Louis, New Orleans, Kansas City, Oklahoma City. Waiting list open in other areas. Send résumé and list of publications to: Philip Eden, President, Associated Appraisers of Earning Capacity, 1303 Walnut Street, Berkeley, California, 94709.

Economists: With continued growth and a new M.A. program in economics the Department of Economics, California State College at Fullerton will have openings in September, 1967, for two additional staff members. Need a Ph.D. economist (rank and salary open) whose primary responsibility will be teaching economic theory at the graduate level in the M.A. program. Ideally (but not necessarily), this person should have an additional interest in teaching in the area of research, development and technological change. Also need a Ph.D. (or near-Ph.D.) labor economist (rank and salary open), with a theoretical and quantitative as well as institutional orientation. This person will be expected to assist in developing a new, interdisciplinary Institute of Industrial and Labor Relations in the College. In general, Department seeks persons with a high degree of technical economic competence, dedicated to teaching, and devoted to continuing professional activity and development. The College, 6 years old and rapidly expanding, is located on the fringe of the Los Angeles metropolitan area. For further details, write (enclosing detailed résumé): Dr. N. Townshend-Zellner, Department of Economics, California State College, 800 North State College Boulevard, Fullerton, California.

Economist: Large midwestern commercial bank is seeking economist to do research and writing on general business conditions and financial markets. A career position with unusual potential, this work involves contact with commercial banking, trust, and bond departments. Minimum requirement: master's degree or equivalent. Salary dependent upon qualifications and experience. Excellent working conditions and benefits. Please submit résumé.

Economics, business administration: Norwich University will have a vacancy and a new position in the Department of Economics and Business Administration beginning in the academic year of 1967-68. One position requires a Ph.D. or D.B.A. in economics or business, with emphasis on managerial economics, systems analysis, and industrial management. Candidate for this opening must have teaching experience, and experience with government or business will be given full consideration. The second position requires at least a master's degree and teaching experience in accounting through the intermediate level as well as principles of economics. Salaries and rank are competitive with other undergraduate colleges in New England. Write to: Dr. Charles J. Jorgensen, Chairman, Department of Economics and Business Administration, Norwich University, Northfield, Vermont, 05663.

Economics, business administration: Teaching, with excellent research opportunities. Quantitative analysis, production management, international economics, micro-economic theory, public finance, business cycles. Salary and rank dependent on qualifications. Ph.D.'s strongly preferred. Apply with résumé to: Dean Leo M. Loll, University of Alaska, College, Alaska, 99735.

Economists: Positions are available at the assistant and associate professor rank in the economics department of a rapidly expanding Canadian university. Needed are a transportation economist and a monetary theorist to teach both graduate and undergraduate courses. Salary and rank will depend on qualifications and experience. The present salary scale is \$8,325-\$11,375 for assistants and \$11,475-\$15,125 for associates. Vacancies also exist for micro and macro specialists to teach at the undergraduate level. Enrollment at the University is 4,000 and is increasing at about 20 percent per year. Appointments are from July 1, with the academic session running from mid-September to mid-April. Salary is paid on an annual basis. The University offers generous fringe benefits such as travel and research grants and sabbatical leave at 80 percent of salary after six years. (In calculating sabbatical, teaching experience elsewhere is transferable up to a maximum of two years.) Teaching load is not more than 9 hours per week. Send detailed résumé to: Dr. F. R. Anton, Head, Department of Economics, University of Calgary, Calgary, Alberta, Canada.

Economics: September, 1967, position open at assistant or associate professor rank in rapidly growing economics curriculum of a state college. Courses to be taught include principles and undergraduate electives (negotiable) as well as first-year graduate level courses (also negotiable). Requirements are Ph.D. or master's with advance credits and college teaching or other allied experience. Salary range is \$7,250-\$12,000 for nine months, depending on education and other qualifications. Summer extra. Write to: Dr. Eugene W. Schooler, West Chester State College, West Chester, Pennsylvania, 19380.

Economists: Permanent teaching positions in an expanding economics department. Salary, \$8,500-\$12,000 for academic year. Openings in several fields of specialization. Ph.D. or near Ph.D. required. For further information, write and send résumé to: Phillip A. May, Department of Economics, School of Arts and Sciences, Northern Michigan University, Marquette, Michigan, 49855.

Economics and business: Rapidly expanding new university, favorably located in the Vancouver metropolitan area, aiming at excellence in undergraduate teaching and strong graduate program, invites applications at all rank levels. Doctorate or near-doctorate required. Favorable academic conditions and advancement opportunities. Additional specialists needed in many areas, including accounting, business finance, commercial law, econometrics, economic history, economic theory, educational economics, international business, management, marketing, mathematical economics, monetary economics, operations research, production, public finance, regional economics, statistics. Write to: Dr. Parzival Copes, Head, Department of Economics and Commerce, Simon Fraser University, Burnaby 2, British Columbia, Canada.

Economics: State University College at Buffalo has two positions, beginning in September, 1967. One is for an assistant professor to teach introductory courses; salary around \$7,500. The second is for an associate professor to teach principles and advanced courses. For this position a Ph.D. is required; salary range is \$9,550-\$11,230. Please write to: Dr. Mohamed El-Beahry, Chairman, Economics—Political Science, State University College, 1300 Elmwood Avenue, Buffalo, New York, 14222. Telephone: 862-5118.

Economist: Ph.D. preferred; doctoral candidates and those with master's degree will be considered. Principles of economics, labor economics, public finance, history of economic thought, macroeconomics. Rank of instructor or assistant professor, depending on advanced degree and teaching experience. Salary range, \$7,500-\$10,000. Liberal fringe benefits. Please send résumé and names and addresses of two references to: Chairman, Department of Economics and Business Administration, Lebanon Valley College, Annville, Pennsylvania, 17003.

Economists, mathematicians, statisticians, operations analysts: Needed by the Research Analysis Corporation to participate in defense-related studies of resource allocation techniques and applications. Areas of interest include systems analysis of defense forces, weapon systems, and manpower and material resources, and its constituent elements of cost-effectiveness analysis and military cost analysis. A strong capability is maintained in computer-assisted model building. Staff members are assisted in acquiring a working knowledge of computer techniques if they do not already have it. Candidates should have at least a master's degree. For additional information, send résumé to: Mr. John G. Burke, Supervisor of Professional Staffing, Research Analysis Corporation, McLean, Virginia, 22101.

Economist: September, 1967. Principles and advanced course to be selected. Twelve-hour load. Assistant or associate. Ph.D. required. Small college of about 2,000 enrollment where emphasis is placed on teaching. Write to: Dick Smith, Head, Department of Social Science, Tarleton State College, Stephenville, Texas, 76402.

Accounting: A full-time accounting instructor is needed beginning January, 1967. Teaching load four or five three-credit courses. Salary and rank based on experience and education. Christian liberal arts college. Write to: Dr. Stewart Lee, Geneva College, Beaver Falls, Pennsylvania, 15010.

Economists: Wellington College (Arts and Science) of the University of Guelph, a rapidly expanding new college, has vacancies at all ranks for economists in most areas of specialization. Ph.D. or near Ph.D. required. Write to: Dr. J. W. Skinner, Head, Department of Economics, Wellington College, University of Guelph, Guelph, Ontario, Canada.

Economists and econometricians: We seek several outstanding men or women for the professional staff of a management consulting firm whose principal clients are blue chip industrial companies. Graduate training in economics at a leading university and several years of experience in business, consulting, or teaching required. New York City location. Ten percent travel. Salary open and depends on qualifications and previous achievements. P335

Tax economists: Office of Tax Analysis, U.S. Treasury Department, has opening for several economists in Washington, D.C. Candidates should have a doctorate or master's degree in economics with some background in public finance and orientation toward quantitative economics. Duties involve studies of the effects of proposed revisions of tax law relating to both domestic and foreign activity. Positions are within the competitive Civil Service at Grades 9 through 15, depending on qualifications, salaries from \$7,696 through \$17,550 per annum. Write to: Director, Office of Tax Analysis, U.S. Treasury Department, Room 4217 Main Treasury, Washington, D.C. 20220.

Accounting and finance: The position of Department Head, Accounting and Finance Department, will be open June 15 or September 1, 1967. Requires a Ph.D. or D.B.A. in accounting or finance, with administrative and teaching experience. C.P.A. and business experience desirable. Rapidly expanding state regional university (13,000 enrollment). Salary competitive and commensurate with qualifications. Contact: Dean Earl A. Roth, College of Business, Eastern Michigan University, Ypsilanti, Michigan 48197.

Economist: For one- or two-year teaching assignment in economics and/or business administration at one of the most progressing international universities. All lectures are in English. Ph.D. or D.B.A. and some teaching experience are required. Salary depends on qualifications, present rank, and experiences. The position may be permanent for Iranian citizens who meet the above qualifications. Contact: Dr. Manuchehr Vessal, Provost, Pahlavi University, Shiraz, Iran.

Economist: New Zealand University requires senior economist. Strictly limited amount of teaching and supervision graduate theses. At least half time available for own research which should preferably relate directly or indirectly to the New Zealand economy or to the Pacific. Appointment for two or three years at professor or associate professor level. Family fares paid. Write: Registrar, University of Otago, Dunedin, New Zealand.

Development economist: Specialist in development and transportation planning. Assignments may be as a member of an integrated group of civil and transportation engineers, economists and cost estimators in the preparation of comprehensive national and regional transportation plans, as well as the analysis of specific transportation investments or individual responsibility for identifying and preparing national investment priorities for developing countries. Requirements for this permanent position would be a Ph.D. in either economics or general business administration, some prior experience on comparable assignments, willingness to permanently relocate outside of the United States or accept travel throughout the world, U.S. citizenship preferred. Salary commensurate with experience. Send detailed curricula vitae, including current earnings and references to: Derish M. Wolff, Director, Development Economics Group, 100 Halsted Street, East Orange, New Jersey, 07018.

Economics and business: Rapidly expanding state college, favorably located in the heart of the Gulf Coast petro-chemical complex and deep water port of major importance. Undergraduate business and economics program with M.B.A. curriculum to be added next year. Economics positions open for fall of 1967: professor and head of Department of Economics, salary range \$10,000-\$12,000; associate professor, salary range \$9,000-\$10,500. Business positions open for fall of 1967: professor, salary range \$10,000-\$12,000; associate professor, salary range \$9,000-\$10,500. Salary quotations are for nine-month academic year; a faculty member will receive one-fourth of this salary if employed during nine-week summer session. Qualifications of Ph.D. and teaching experience. Write to: Dr. Armand L. Perrault, Dean, Division of Commerce, McNeese State College, Lake Charles, Louisiana, 70601.

Economist: Resource economist in water and land use planning demand studies, projections, and project evaluation. Position immediately available. Master's degree in economics or planning with a major in economics, plus work toward a doctor's degree. A total of three years of graduate training required. Two years of experience may be substituted for graduate work beyond the master's degree. Salary range \$8,500 to \$11,050. Fringe benefits include annual increment, health benefits program with major medical coverage, vacation and sick leave provisions, retirement program with life insurance, 40-hour week. Excellent opportunity with nationally recognized river development government agency. Send résumé to: Delaware River Basin Commission, Administrative Division, P.O. Box 360, Trenton, New Jersey, 08603.

Economics and business: The University of Lethbridge (a provincial university) invites applications for two teaching appointments available for Ph.D.'s or near-Ph.D.'s in the field of economics (mathematical economics, statistics, and international economics) and business administration (accounting, management, and business finance). Rank and salary are open. Please submit complete résumé to: Mr. Carl B. Johnson, Acting President, University of Lethbridge, Lethbridge, Alberta, Canada.

Economists: With continued growth and a new Department of Economics in the School of Arts and Sciences, California State Polytechnic College, Kellogg-Voorhis, Pomona, California, will have at least two positions open in September, 1967 (rank and salary open). Immediate needs are for instructors capable of teaching econometrics, programming, and forecasting at the undergraduate level. Also expected to teach some sections of the basic principles course. Ph.D. preferred but not mandatory. Especially interested in young graduate students completing degree requirement or economists with or without degree but with experience in quantitative economic analysis. For further information write: George Galbreath, Head, Department of Economics, California State Polytechnic College, Pomona, California.

Undergraduate economics: Liberal arts college for women expects to make appointment to begin September, 1967. Introductory and advanced undergraduate courses. Ph.D. preferred; master's required. Rank and salary dependent on training and experience. Write to: C. T. Ruddick, Vice-President, Lake Erie College, Painesville, Ohio, 44077.

Teaching opportunities abroad: University positions, instructor to professor level, in the developing nations of Asia, Latin America, and primarily Africa. Two-year contracts. Salary dependent on level and location; transportation provided. Write to: Overseas Educational Service, 522 Fifth Avenue, New York, New York, 10036. An equal opportunity employer.

Economists: Positions available with TVA's Regional Studies Staff in Knoxville, Tennessee, for candidates interested in regional economic development and economic planning. Duties involved are: to assist in formulation of a regional growth simulation model in program evaluation, particularly with respect to waste management systems; to test and evaluate results; to analyze problems in corporate planning of regional development programs; to assist in evaluating research problems submitted by line divisions; to analyze program functions and suggest procedures for evaluating program contributions to regional economic development. Candidates should have at least a master's degree. Salary \$8,100 to \$13,025. Send résumé to: Chief, Employment Branch (AER), Tennessee Valley Authority, Knoxville, Tennessee, 37902.

Accountants: With continued growth and expanding academic programs, the Accounting Department, Texas A. and M. University has openings for two additional staff members. One, an outstanding tax and auditing specialist with a capability in computers as related to accounting in general and auditing in particular. Applicants should possess terminal degree and preferably be in mid-career and interested in a balanced program of teaching, research, and publications. Salary to \$16,500 for nine months with opportunity for additional summer term teaching at a comparable rate. Second, an assistant professor interested in principles and theory, cost, and computer applications in accounting. Applicant should possess terminal degree. Salary to \$10,750 for nine months with opportunity for additional summer term teaching. Applicants for both positions may send credentials to: Dr. Jack W. Coleman, Head, Accounting Department, School of Business, Texas A. and M. University, College Station, Texas, 77843.

Finance: With continued growth and expanding programs, the Finance Department has an opening for an additional staff member. This is for an assistant professor with salary to \$10,750 for nine months with opportunity for additional summer term teaching. Requirements call for a terminal degree. Appointee should be interested in specialization in the institutional aspects of finance. Applicants for this position may forward their credentials to: Dr. John E. Pearson, Director, School of Business, Texas A. and M. University, College Station, Texas, 77843.

Operations research, mathematical economics: Position open at instructor-assistant professor level in a rigorous graduate program in industrial administration. Engineering background or industrial experience desirable. Should be interested in teaching courses in decision theory, statistics, operations research, and an undergraduate course in quantitative economics. Top salaries. Write to: Alfred L. Thimm, Director, Graduate Program in Industrial Administration, Union College, Schenectady, New York, 12308.

Economics: New state university. Openings in Department of Economics, all fields. For more information, write: Howard Mahan, Chairman, Social Sciences Division, University of South Alabama, Mobile, Alabama, 36608.

Director economic-marketing research: A consumer product research and promotional organization supported by 15 Latin-American countries is seeking a person to head up six-man department of international marketing and economic research. Must have advanced degree, preferably doctorate, in economics, marketing, chemistry, and agronomy. Interest in South American and Spanish-speaking capability desirable. Location in New York City. Salary consistent with experience and qualifications plus liberal benefits. Write in confidence to: Case and Company, Inc., Management Consultants, 600 Fifth Avenue, New York, New York, 10020.

Economics: Small liberal arts college seeks Ph.D. in economics for August, 1967. Some combination in international trade, comparative economic systems, marketing, history of economic thought, or labor economics desired. Institution is state supported, new, and emphasizes opportunity for small classes and experimental approaches in instruction; rank and salary open. Address inquiries to: Roy Wood, Head, Department of Economics, Asheville-Biltmore College, Asheville, North Carolina, 28801.

Economists: Applications invited for various positions in rapidly expanding program. Salary and status dependent on qualifications and experience. Salaries up to \$19,000, pensionable, fringe benefits. Send applications to: Dr. Rawle Farley, Chairman, Department of Economics, State University of New York, Brockport, New York, 14420.

Statistics, macroeconomics, principles of economics: One of the younger professors is being given a leave of absence for the academic year 1967-68, so that he will be able to complete his doctoral dissertation. We seek a professor (Ph.D. or Ph.D. candidate) for a one-year appointment to teach the following courses: fall, 1967, two sections of principles of economics and two sections of introductory statistics; spring, 1968, two sections of principles of economics, one section of macroeconomics, and one section of intermediate statistics. While the term of employment is for one year only, Loyola College is in the process of expanding its program, and it may be possible to retain a suitable applicant on a long-term basis. Salary is open, because of the unusual circumstances. Loyola College is operated by the Jesuit Fathers. However, the religion of the applicant is not a material factor. We have a student body composed of Catholics and non-Catholics. Contact: Rev. Henry Lavin, Dean, Loyola College, 4501 North Charles Street, Baltimore, Maryland, 21210.

Economics: Several new permanent positions in eighteen-man economics department at a rapidly growing state university (16,500 students) with increasing emphasis on upperclass and graduate education. Positions can be filled at any rank and in most fields of specialization. Ph.D. in economics required for all positions. Senior ranks require teaching experience and record of publication as well as interest in working with graduate students. Opportunity to combine specialty teaching with research work under reduced class load. Nine-month salary ranges from \$9,000 to \$17,000-plus. Summer teaching and research grants commonly pay one or two months' additional salary. Send résumé and references to: Jack W. Skeels, Department of Economics, Northern Illinois University, De Kalb, Illinois, 60115.

Transportation economist or transportation specialist: U.S. Army Corps of Engineers, Civil Works Directorate, requires several transportation economics or transportation specialists to fill staff positions in division and district offices in various parts of the country. Positions are from grade level GS-5 (\$5,331) to GS-13 (\$12,873) and are a part of the federal Civil Service program. Basic requirements are a degree in economics or business administration and appropriate experience or training for performing the following duties: supervises or produces economic evaluation studies of proposed waterway or harbor improvements; structures potential area of influence of proposed improvement, determines movements of commodities in area of influence, and assesses economic efficiencies of moving these commodities by various carrier modes—water, rail, road, and pipeline. Should be familiar with cost and rate structures of these carrier modes as well as evolving technologic changes affecting their interrelationships in an overall transportation system for a region and for the entire nation. Applicants should apply to: Mr. N. A. Back, Chief, Economics and Evaluation Branch, Civil Works Directorate, Office, Chief of Engineers, Washington, D.C., 20315.

Economists and regional economists: U.S. Army Corps of Engineers, Civil Works Directorate, requires approximately fifty qualified economists to fill newly established staff positions in division and district offices in various parts of the country. Positions are from grade level GS-5 (\$5,331) to GS-13 (\$12,873) and are a part of the federal Civil Service program. Basic requirements are: a degree in economics or closely allied field and appropriate experience or training for performing the following duties: identification of the need for and the benefits of water and related land resource developments for such purposes as navigation, water supply, water quality, flood control, power, shore protection, irrigation, recreation, and fish and wildlife enhancement; comparative advantages of alternate means for meeting water resource needs; the application of economic data and procedures in the formulation of comprehensive plans for river basins and multipurpose projects; the role of water resources in regional and area development; and the allocation of costs among project purposes. Applicants should apply to: Mr. N. A. Back, Chief, Economics and Evaluations Branch, Civil Works Directorate, Office, Chief of Engineers, Washington, D.C., 20315.

Economists: Federal agency has openings for two economists, GS-7 (\$6,451), GS-9 (\$7,696), GS-11 (\$9,221), or GS-12 (\$10,927 per annum) to start. Training in statistics required. One of the openings requires additional preparation in mathematics. Candidates for higher grade positions must have experience in business economics or economic research. Submit résumé to: Dr. John T. Walter, Director, Economic Studies Division, Post Office Department, Washington, D.C., 20260.

Economics: Ph.D. with teaching experience, associate or full professor, to head department of small liberal arts college. Nine months' salary range \$7,500 to \$11,000, liberal fringe benefits. Position open September, 1967. Write to: President L. Vernon Caine, Illinois College, Jacksonville, Illinois, 62650.

Business administration: Due to an expanding undergraduate and graduate program, positions are open for faculty in the areas of accounting, finance, production management, marketing, business communications, statistics, and office education. Ph.D. required. Prefer research-oriented persons. Write to: Dean Robert L. Thistlethwaite, College of Business, Northern Illinois University, De Kalb, Illinois, 60115.

Economist: September, 1967. Principles and advanced course. Twelve-hour maximum. Assistant or associate. Rank and salary dependent upon background. Ph.D. or near Ph.D. required. Coeducational college of approximately 1,800 enrollment, located 25 miles north of Boston. Write to: Dr. Edward J. Burns, Chairman, Department of Economics, Merrimack College, North Andover, Massachusetts, 01845.

Economists: Many developing countries turn to the United Nations and its specialized agencies for help and advice in dealing with their problems. Consequently, the United Nations needs the services of highly qualified economists in almost every field of specialization for its technical assistance and pre-investment programs. These overseas assignments in the developing countries vary from a few months to several years, although most of them are for "one year with possibility of extension." Positions with the U.N. Development Program offer economists with graduate degrees and 10 or more years of practical experience an unusual opportunity to participate in the stimulating programs of economic development which characterize a large number of emerging countries. Such assignments often can be fitted into the university professor's sabbatical year; for longer assignments universities have been willing to grant leaves of absence. This program provides a unique opportunity for university economists to fill interesting and worthwhile jobs which will benefit the developing countries and contribute to their academic careers. The United Nations also seeks economists and econometricians for research and operational posts at its headquarters and Regional Economic Commissions. These posts require candidates for an M.A. or Ph.D. in economics or econometrics and several years of experience which has involved substantial economic research. Most appointments are for a minimum of two years, although a limited number are for shorter periods and can be worked into sabbatical years. U.S. citizens should send résumés to: Director, Office of International Organization Recruitment, Department of State, Washington, D.C., 20520. Non-U.S. citizens should apply directly to: Office of Personnel, United Nations, New York, New York, 10017.

Labor economists and statisticians: Attorneys throughout the U.S. are discovering that expert economists and statisticians can provide valuable assistance in ascertaining the extent of monetary losses suffered because of wrongful injury or death. General qualifications for those desiring to engage in this rewarding professional activity include university faculty status of associate professor and above, labor economic orientation, and located near a major city. Established regional economic consulting organization active in this field and the general consulting business is expanding nationally. Both ownership participation and associate opportunities available. If interested, write to: D. Carl Deiter, President, Economic and Statistical Consultants, Inc., Box 17184, Tampa, Florida, 33612.

Economists: Office of International Operations, Internal Revenue Service, has unique and intellectually challenging career opportunities for economists in Washington, D.C. Duties involve the application of economic analysis to intercorporate affairs between related corporations to determine whether they reflect market or arm's length standards. Function is to provide analysis and recommendations on the "reasonableness" of intercorporate prices, and whether or not the corporations involved have failed to clearly reflect their true taxable income. These studies cover the entire spectrum of business activity and will have an important bearing on the development of tax law guidelines and precedents involving intercorporate pricing in the expanding field of international commerce. Positions are available at entrance salaries ranging from \$10,000 to \$15,000. Position and starting salary will depend upon educational background and professional experience. For further details, write to: Director of International Operations, Attention of Chief, Economic Advisory Branch, Internal Revenue Service, Washington, D.C., 20225.

Economics and department head: Opening for Ph.D. with teaching experience in growing economics department. Teaching assignments primarily in fields of general economics, statistics and quantitative methods, labor, growth and comparative economics. Currently a two-man department. College located ideally in rural community but only one hour from Philadelphia. Retired applicants welcome. Send résumé to: D. E. Strick, Dean, Millersville State College, Millersville, Pennsylvania, 17551.

Economics, temporary position: Opening for 1967-68 school year for Ph.D. candidate. Full-time or part-time appointment available. Teaching assignments in basic economics, public finance, comparative economics. Ten miles from Lancaster; 65 miles from Philadelphia. Ideal for dissertation-writing student. Send résumé to: D. E. Strick, Dean, Millersville State College, Millersville, Pennsylvania, 17551.

Economist: Liberal arts college, Catholic auspices, urban residential location. Enrollment 1,850. Day and evening divisions. Emphasis upon teaching and personal relationship with students. Distinctive program of concentration featuring undergraduate seminars and fostering independent study. Desire a man with Ph.D. or close to a doctorate. Must be able to teach also in business administration. Labor economics interest preferred. Appointment range: instructor-associate professor. Salary competitive; depends on experience. Submit résumé to: Chairman, Department of Business and Economics, Bellarmine College, 2000 Norris Place, Louisville, Kentucky, 40205.

Economist: Michigan church-related (Methodist) four-year liberal arts college seeks Ph.D. or Ph.D. candidate for teaching of principles and intermediate economics courses. Flexible course assignment; assistant or associate professor to begin September, 1967; generous fringe benefits. P336

International finance, public finance and fiscal policy, national income accounting, economic development, economics of welfare, regional economics: Man, 38, married; M.A., additional work towards Ph.D. Fellowships; languages; 9 years of progressive research experience; publications. Seeks research position. Willing to relocate. E1625

Micro-theory, managerial economics, mathematical economics, marketing theory, international trade: Man, 27, married, Scandinavian; M.B.A., doctorate in June, 1967. Four years of university teaching experience. Seeks assignment as visiting lecturer for 1967-68 at U.S. university or college. E1626

Micro- and macroeconomics, international economics, money and banking, labor economics, agricultural economics, public finance: Man, 47, married; M.A., Ph.D. dissertation well under way, degree anticipated in fall, 1967. Desires teaching and/or research position. Available in April, 1967. E1627

Management, business law, business organization: Man, 27, married; B.S. (industrial organization), M.B.A. (marketing), J.D. College teaching and industrial experience. Desires teaching position with increased opportunity. Available in September, 1967, or September, 1968. E1628

Statistics, money and banking, economic development, economic theory: Man, 33, married; all Ph.D. requirements completed except thesis. Three years of research experience. Desires teaching position or research position with opportunities for research in or close to New York City. Available in fall, 1967. E1629

Mathematical economics, econometrics, statistics, interindustry analysis, macro- and microeconomics: Man, 31, married; Ph.D. Some teaching and research experience. Desires teaching or research position. Available in fall, 1967. E1630

International economics, managerial economics, government and business, comparative economic systems, principles: Man, 42, married; Ph.D. Experience as department chairman; modest publications. Available in September, 1967. E1631

Micro- and macroeconomics, history of economic thought, public finance, money and banking: Man, early 40's, married; Ph.D. Administrative, consulting, and teaching experience; presently department head and associate professor. Would like greater administrative responsibility and full professorship. Available in summer or fall, 1967. E1632

Statistics, macro and micro economic theory, business economics and public policy, quantitative methods, marketing research, economic development, regional planning: Man, 45, married; Ph.D. Research and teaching experience. Desires teaching or research position. E1633

Statistics, microeconomics, macroeconomics: Man, 28, married; B.B.A., M.A. in Economics. Three years of experience in analytical and research work, especially in the application of advanced technology to various areas of business. Also worked extensively with trade associations in the development of statistical and marketing programs. One year of teaching experience. Desires a highly responsible and challenging position as a research analyst or a research specialist with either an industrial concern or a consulting group. E1634

Finance, management, mathematics, quantitative methods in decision making: Man, married; undergraduate training in chemistry and mathematics, Ph.D. in business administration. Diversified teaching experience; also experience in teaching adults beyond the college age; business experience as business manager, chemical purchasing agent, and consultant. Currently professor and chairman of business division. Desires teaching and/or administrative position at undergraduate or graduate level; also interested in management development and corporate long-range planning. E1635

Labor economics, economic thought, comparative economic systems, micro- and macro-economics, economic principles, international trade, public finance, money and banking: Man, 31, married; B.B.A., M.A. from leading university. Five years of teaching experience. Good liberal arts background. Member of major professional associations. Fluent in Spanish and French. Prefers medium-size and large cities. Presently employed in large state university as assistant professor. Seeks teaching position with university or college. Willing to go abroad, Europe or Latin America. Available in June or September, 1967. E1636

Economic and business statistics, econometrics, economic theory, economic development, transportation: Man, 43, married; Ph.D. Adequate publications; 14 years of full- and part-time teaching and research experience; 2 years of full-time research abroad and 2 years of administrative experience. Seeks teaching and/or research position. Available in September, 1967. E1637

Economic theory, comparative economic systems, money and banking, economic growth, international trade, American economic history, international financial institutions: Man, Indian citizen, 37, married; B.A., M.A., LL.B. (Bombay), Ph.D., American University. Year and a half of teaching experience; 5 years of experience as economist with embassy; 3 years experience as financial analyst and manager-economist with American companies in India; published 3 articles and submitted 11 papers. Desires teaching position beginning fall, 1967. E1638

Economic development, international economics, monetary economics, micro- and macroeconomic theory: Man, 31, Indian, single; B.Com. (Honours), M.A., Ph.D. (U.S.A.). Three years of teaching experience as a graduate assistant; 3 years as an assistant professor. Publications in leading U.S. and European learned journals. Currently an assistant professor at a state university in U.S. Seeks permanent or temporary teaching position in a Canadian university. Available in June, 1967. E1639

Macro- and micro-theory, economic history, history of economic doctrines, development and international economics, money and banking, public finance: Man, 31, married; Ph.D., 1965. Five years of college teaching experience; Romance languages; some publications. Desires teaching position allowing possibility to continue research. E1640

History of economic thought, development of industrial civilization, business and society, micro economic theory, principles, interdisciplinary social science: Man, 30; B.A., M.A. in economics, Ph.D. in general education (social science) with emphasis in economics to be completed by August, 1967. Five years of teaching experience. At present assistant professor at midwestern university. Desires teaching position. Available in September, 1967. E1641

Principles, labor economics, money and banking, history of economic thought, micro- and macroeconomics, elementary statistics: Man, 38, married; Ph.D. Seven years of teaching experience. At present associate professor at large state college. Desires teaching with opportunity to do research. Willing to relocate. Available in June or September, 1967. E1642

Principles, economic development: Man, 41, married; B.S. in chemistry, M.A. in economics, 50 semester hours beyond M.A. in economics and history of science and technology. Two years of college chemistry teaching; 10 years of experience as industrial chemist; 4 years of college economics teaching. Currently an associate professor of economics but desires any position at or near a university that would make possible completion of doctorate. David H. Burger, 34 Frawley Drive, Fulton, New York, 13069, 315-593-2486.

International economics, monetary economics: Man, 46; M.B.A., Ph.D. Professor at large eastern university; author with expertise and knowledge of languages. Seeks interesting teaching position close to research libraries or international-financial assignment. Available in September, 1967. E1643

Micro- and macroeconomic theory, industrial organization and social control, comparative economic systems: Man, 29, married; B.A. M.A. in economics, with substantial additional work towards Ph.D. Fellowships. Omicron Delta Epsilon. Three years of full-time teaching experience with assistant professor rank at a state college. Seeks position in teaching or with government. Available in June or September, 1967. E1644

Principles, labor economics, collective bargaining, micro theory, government and business, public finance: Man, 30; prestige Ph.D. Six years of teaching experience. Desires position for summer of 1967 only. E1645

Mineral economics, industrial organization, microeconomic theory, economic development: Man, 27, married; B.S.(mng.eng.), M.S.(mng.eng.), working toward a Ph.D. in mineral economics at Penn State, requirements completed except defense of dissertation. About 3 years of industrial experience; more than 3 years of research experience. Seeks teaching-research position. Available in July, 1967. E1646

Economic principles, economic development, monetary theory: Man, 27; M.A. from an Indian university, A.M. (economics), University of Chicago. Research assistant, Department of Political Science, Community and Family Study Center, Department of Sociology, Department of Psychiatry, University of Chicago. Seeks teaching or research position either in Canada or the United States. Available immediately. E1647

International economics and business, economic theory and thought, economic development, growth, and planning, economic systems: Man, 51; Ph.D. Ford Foundation fellowship; publications, including one book. Now on a university faculty. Desires full professorship in a progressive institution. E1648

Money and banking, international finance, economic analysis, economic policy: Man, 44, married; Ph.D. Five years of university teaching experience; 15 years of economic research in business; 2 years as government economist; modest publication record, including two books. Seeks stimulating position in teaching or research. Available at end of 1967. E1649

Principles, money and banking, international trade, industrial organization: Man, 26, married; M.A., Ph.D. course work completed in July, 1967. Publications; fluent Spanish and German. Seeks position outside U.S. or, if in U.S., at international organization. E1650

Regional economics, public finance, monetary theory and policy, micro and macro theory, economic thought, development of mature economies: Man, 27, married; all course work toward Ph.D. Teaching and research experience. Desires teaching and/or research position, prefers Washington, D.C., New York State, or Canada. Available in summer or fall, 1967. E1651

Industrial organization, economic growth, planning advanced theory: Man, 42; Ph.D. Presently professor and chairman of department of economics in Indian university, language of instruction English; with a maximum of two years leave. Fourteen years of teaching and research; number of publications in pertinent fields, including two books on industrial organization in India. Desires teaching position in United States or Canadian college or university for one or two years; purpose is the acquiring of experience abroad, not the improvement of income. Leave will start with beginning date of position. Family will not accompany applicant. Available at any time after March, 1967. E1652

Economic development, economic planning, money and banking, micro and macro theory, economic thought, international economics, comparative economic systems, principles: Man, 33, married; M.A., Ph.D. Modest publications; widely traveled. Two years of research experience in a highly responsible administrative position. Presently assistant professor in a large midwest Canadian university on a temporary assignment. Desires teaching and/or research in a progressive institution in Canada. Available in June, 1967. E1653

Public finance, money and banking, principles, history of economic thought: Man, 29, married; B.S.(accounting), M.B.A., Ph.D.(economics) expected in June, 1967. Research fellowship; several teaching fellowships; 3 years of university teaching experience as instructor in economics, undergraduate. Desires position either in teaching, administration, research, or some combination. Prefers New England but would consider other locations. Available in September, 1967. E1654

Social accounting, international economics, micro and macro theory, economic thought, economic development, comparative economic systems, principles: Woman, 31, married; M.A., Ph.D. Widely traveled. Three years of research experience; 2 years of teaching in a high school. Desire teaching and/or research in a progressive institution in Canada. Available in September, 1967. E1655

Labor economics, macro and micro theory, money and banking, history of thought, principles: Man, 43, married; B.S.(economics), M.A.(economics), candidate for Ph.D. Ten years of full-time college teaching; research experience; publications. Small college preferred. E1656

Principles, labor, consumer comparative economics, history of economic thought: Woman, retired after 20 years of college teaching in one institution; German Dr. rer. pol., M.P.A. (U.S.). Seeks position with college in East on a year-to-year basis. Available in September, 1967. E1657

ABBA P. LERNER

DISTINGUISHED FELLOW

1966

Abba Lerner has contributed significantly to progress in more different fields of economics than any other living economist: among them, welfare economics, public finance, employment theory, inflation, international trade, wages, monopolistic competition, capital, and interest. In every case his contributions have been impressive and in several, fundamental. Modern welfare economics, for example, is heavily indebted to him; modern international trade theory owes much to his early articles. Throughout this extraordinary series of achievements, he has used the simplest and rarest of analytical tools: a mind of astonishing clarity and rigorousness. Often charged with being impractical—as, for example, when he advocated functional finance, or when he undertook to demonstrate “the *rapprochement* between socialism and capitalism”—he has lived to see many of his apparently impractical ideas come to life. He is an expositor and a teacher of rare ability, and he repeatedly demonstrates to us all the virtues in economic analysis of logic, precision, directness, and simplicity, combined with grace, style, humor, and wisdom.

A PERMANENT INCOME THEORY FOR INVESTMENT: SOME EMPIRICAL EXPLORATIONS

By ROBERT EISNER*

We have learned, perhaps a bit belatedly, that no meaningful, stable relation is to be expected between some ill-defined, really "transitory" income and consumption. An increase in income for one week cannot be expected to have the same effect upon consumption as an equal increase in the rate of income over a period of a month or year or a decade. The extent to which consumption is related to "income" must depend upon the length of time over which income is averaged or integrated.

At the root of the problem, however, is a more fundamental issue, of critical importance in the marriage of the economic theorist and the working econometrician. Our economic theory reminds us again and again that bygones are bygones. Current or past values of variables, no matter over how long a period they are measured, are bygones except insofar as they establish initial conditions and expectations of *future* variables. Thus, in the consumption function we may expect measured current or past income to be relevant insofar as it affects current wealth and expectations of future income. As has been stressed by Modigliani and Brumberg [7] the relation between consumption and measured income in any body of data will depend upon the relation, in that body of data, between measured incomes and the initial wealth and expected future incomes or, in Milton Friedman's terminology, the relation between measured income and "permanent income."

*The author is professor of economics, Northwestern University. An earlier version of this paper was presented to the First World Congress of the Econometric Society in Rome, September 1965, and I am deeply indebted to the economists, research workers, and computer programmers who have labored with me in its preparation. They include Marjorie Bechtel, Betty Benson, Robert M. Coen, Joel Fried, Jon Joyce, Elsie Kurasch, Albert Morris, Hugh Pitcher, Judith Pitcher, Jon Rasmussen, Jay Salkin, Kenneth Smith, and Patricia Wishart. Particular credit should be given to the McGraw-Hill Publishing Company department of economics and to Margaret K. Matulis of McGraw-Hill, who have made available the original data. The research has utilized the facilities of the Computing Center and the Econometrics Research Center of Northwestern University. It has enjoyed the important financial support of a series of grants from the National Science Foundation.

My own exploration of the varying estimates that might be expected from different structurings of data began with confirmation of a hypothesis by Friedman [5] that, if cross sections of households were subdivided into groups relatively homogeneous in permanent income, transitory components were likely to dominate the intragroup variances and bias downward the estimates of slope and elasticity of the consumption-income relation. I further observed that, when the group means were taken as observations, slopes and elasticities were both higher than those calculated from the cross sections of individual households, and consumption was indeed estimated to be an almost homogeneous (linear) function of income [1].

It is reasonable to expect the same phenomena in estimates of the investment function. Again, bygones must be bygones. This is true, after all, regardless of the variables that we consider significant for investment. Neither output (or sales), nor earnings, nor rates of interest, nor technological change should affect the current or future rates of investment except insofar as they affect initial conditions or expectations of relevant future variables. Initial conditions may of course include the existing capital stock and states of technology and finances, which have been determined by past variables. They may even include an immediately past rate of investment which can only be changed rapidly at considerable cost. But it is still the initial conditions and expected future paths of variables to which the investment function must relate. Estimates of the investment function which use past values of variables as observations will be as meaningful and stable as the relations among those past variables and the true arguments of the investment function.

A prime determinant of capital expenditures must be changes in expected future demand or the relation between expected future demand and existing capacity. A sophisticated or flexible application of the acceleration principle, by which the rate of investment demand depends upon the acceleration of the rate of the demand for output, will reflect this underlying relation between expected demand and capacity to the extent that it measures variations in past demand which are not merely bygones but which may be viewed by business decision-makers as "permanent." Thus, one could expect little relation between current investment and the current rate of change of output or the rates of change of output over a short preceding period of time. One should, however, expect to find a much more substantial relation between current capital expenditures and measures of the rates of change of demand over a considerable number of past periods.

Further, estimates of the investment function based upon the covariance of capital expenditures and measures of changes in demand

will indicate higher coefficients of demand variables where the variance and covariance relate more to "permanent" components of demand. In previous work I have confirmed this hypothesis by comparisons of estimates of the relation between investment and previous changes in sales on an intraindustry, interfirm basis with similar estimates on an inter-industry-year basis [2]. On the assumption that average changes in sales of all of the firms in an industry in a given year would prove a better proxy for future demand relevant to investment than would the sales experience of an individual firm, the industry-year regressions should, as they did, yield the higher sales-change or "accelerator" coefficients. In other work I have also noted that expectations of future sales changes as well as the ratios of actual to desired utilization of capacity, as reported by firms, related in the expected positive manner to actual capital expenditures [3].

I. Scope of the Present Paper

In the present paper I shall extend my earlier work in several directions. (1) I shall include a sufficient number of years of observations to permit critical comparisons of pooled cross section and time series data and shall present appropriate F-ratios for differences in regressions, along with standard errors of differences in coefficients for both time series and cross section decompositions of the total sums of squares. (2) I shall expand the work with explicit variables measuring expected sales changes and business views of the relation between their actual and desired utilization of capacity. (3) I shall introduce for the first time in large bodies of data of this kind variables measuring market evaluations of expected earnings (and implicitly expected demand). This last will be made possible by calculation of a variable defined as the sum of bonded indebtedness and the market value of outstanding shares of common and preferred stock, a variable which we shall denote as "the value of the firm."

It seems appropriate to describe briefly the rather remarkable collection of data on which this paper is based. Previous reports involve estimates from individual firm responses in McGraw-Hill capital expenditure surveys from 1949 through 1958, but chiefly from 1955, when responses became somewhat more numerous, supplemented by collateral financial data for each of the McGraw-Hill respondents, coded in such a manner as to preserve the confidential character of the surveys. For the work here reported upon, with intensive effort and considerable use of high speed computing facilities the body of data was brought up through the year 1962. We were therefore able to analyze eight years of capital expenditure data as well as various collateral statistics extending from 1962 back to as far as 1946. In addition, an

entirely new body of data bearing on the value of the firm has now been collected for the years 1959 through 1962.

We have information on an individual firm basis for some 800 firms,¹ a major portion of the McGraw-Hill sample, accounting for a substantial amount of the capital expenditure and general economic activity in the private sector of the U.S. economy. The data are also being used in estimates of production functions,² the role and formation of anticipations, inventory investment, and a number of related matters. On this occasion, however, we shall report only on certain preliminary findings with respect to capital expenditures.

II. Cross Sections and Time Series and Measures of Expected Future Demand

Among the variety of estimates of parameters of investment functions which have been presented, it has been noted, particularly, that estimates derived from cross sections of data have differed from those obtained from time series. (See, for example, Kuh [6].) Estimates have also differed when derived from time series aggregates, time series of industry data, or time series of data of individual firms. Production function estimates have varied as well, when derived from cross sections of individual firms, "two-digit" or "three-digit" industries, states, or nations. A common element, I submit, in all of these differences is that in each case the observed variables are in a different relation to the unobserved variables from which we start in our economic theory. In particular, with regard to the investment function, the variance in past sales changes or profits or other variables may be related to expected demand or the expected profitability of investment in quite varied ways among different types of cross sections and time series. It will be one purpose of this paper to use the extensive and multidimensional body of data at our disposal to explore these differences as they relate to certain plausible hypotheses about economic behavior. We shall hence present estimates of parameters of the investment function based upon least squares regressions of the following structurings of the same basic data:

1. Firm time series for firms with more than one year of observations, utilizing deviations of observations of each year around the mean of the firm's observations for all years. These deviations are summed for all firms.
2. Industry time series, involving deviations about the means for all

¹ Firms for which capital expenditure data of any single year are available, however, number only between 450 and 710. See Appendix A for a tabulation of observations used (in Tables 1, 2, and 3) by industry and year.

² Reported upon in [4].

years within each industry, where each observation is the mean of all observations of individual firms within the industry during the year, weighted by the number of firms. These deviations are summed for all industries.

3. Firm cross sections within industries, using deviations about the means of observations within each industry for each year, summed for all years and all industries.

4. Firm cross sections across industries, which use deviations about the overall mean for each year, summed for all years.

5. Cross sections of firm means across industries, utilizing the means of the observations of each firm with more than one year of observations, involving deviations of these firm means about the overall mean of underlying individual observations.

6. Industry cross sections, involving deviations of industry-year-mean observations about the means for all industries for each year, summed for all years.

7. Overall deviations of observations from their means, where observations differ as to firm or industry as well as to year.³

It will be our purpose not only to offer empirical evidence for caution in interpreting any particular set of estimates by noting the differences among them, but also to suggest and test the role of a permanent income hypothesis in explaining the differences. At least with regard to demand variables, one should expect that variation over time in the experience of an individual firm is likely to have the smallest relative "permanent" component. Since investment must be undertaken on the basis of expected profitability over long periods of time, firms may be expected to be cautious in altering their rates of investment in response to relatively short-term fluctuations in demand. By utilizing a distributed lag function, estimating separately and without constraint the coefficients of individual lagged variables, we may expect to pick up some longer run effect but we should still look for the role of demand variables to be obscured significantly in firm time series.

Turning to liquidity variables, a priori reasoning is somewhat less certain. If imperfections in capital markets (perhaps particularly for small firms) tie financing to current or past profits, capital expenditures may proceed at a more rapid rate when the flow of profits has been more rapid.

We might also expect a relatively reduced role for demand variables in cross sections of the firms within each industry although perhaps a greater role than in the firm time series discussed above. For here we

³ Appendix B states algebraically the precise nature of the deviations used in the various regressions.

may argue that business decision-makers are unlikely to view the difference between their own firm's experience in a given year and that of their industry as clearly indicative of differences in long-run expectations which should affect capital expenditures. The force of this argument is somewhat weakened by the fact that our "industries" are quite large industry-groups sufficiently heterogeneous in character to encompass a wide variety of experience.

Regressions of industry time series should perhaps show a stronger role for demand than those of firm time series. This role may still be restricted, however, by the probability that much of the interyear, intraindustry variance in demand over the years under study was likely to be viewed as transitory. One should clearly expect estimates suggesting a greater role for demand variables in longer time series which include great long-run variations in demand.

The role of past demand should show up most clearly in interindustry cross sections. At the firm level this may become apparent in cross sections across industries but permanent effects may be partially obscured by the "noise" or errors in variables of individual year observations. Year-to-year transitory fluctuations should, however, tend to wash out in cross sections of firm means, which would capture more of the longer-run differences among firms. And similarly, to the extent that demand has been growing more rapidly in one industry than in other industries, firms within that more rapidly growing industry are more likely to have favorable long-term demand expectations than are firms elsewhere whose growth in demand happens to have been larger than the mean of their average-growth industry. Business thinking, on what may appear to be an unsophisticated level to the scientific observer, runs frequently in terms of accustomed "shares of the market." This, however, may actually be a reflection of the statistical law of large numbers. The experience of all the firms in a given industry may be a better estimator of future prospects of an individual firm than may the single past experience of that firm itself.

We should expect that, if past demand enters into the investment function as a proxy for the ratio of expected future demand to existing capacity, the role of past sales changes will be supplemented or partially replaced by variables dealing explicitly with expected future sales changes, the utilization of existing capacity, and market evaluation of changes in expected future earnings. To examine these factors, we shall make use of responses to McGraw-Hill questions regarding expected changes in sales over four-year and one-year periods and to questions bearing on both actual and preferred rates of utilization of capacity. In the case of the latter we have constructed a variable (uc), defined as the ratio of actual to preferred rate of utilization of ca-

capacity, which may be taken as a direct measure of the pressure of current demand upon capacity. We have also utilized our financial data to construct measures of the ratios of (1) earnings to market value of the firm (r), (2) market value of the firm to net worth plus depreciation reserve plus bonded indebtedness (m), and (3) the change in market value of the firm (Δv).

III. *The Variables and Methods of Analysis and Presentation*

We shall hence report results of five sets of regressions involving individual firms—time series, cross sections within industries, cross sections across industries, cross sections of firm means, and overall⁴—and, where there are sufficient observations, three industry regressions—time series, cross sections, and overall. As in previous work, it has been deemed advisable to exclude observations containing extreme values of any of the variables. Upper and lower bounds of acceptable intervals were established on the basis of preliminary analysis of means and standard deviations. Intervals were generally set so that inclusion of at least 99 per cent of the values on each variable might be expected.

No attempt was made to utilize information from incomplete observation vectors. Hence a considerable number of observations were rejected because of missing information on only one or several variables. The "Definitions and Sources of Variables and Intervals for Accepted Values," which follows shortly below, describes precisely the variables utilized and indicates the intervals for acceptable values. Each table reports the number of observations rejected because of extreme values of at least one of the variables in the observation vector. In the time series, which are pooled regressions of deviations about the means of observations for individual firms and industries, respectively, a degree of freedom is lost for each firm or each industry included. Cross section regressions across industries were in effect pooled regressions of deviations about the means for each year; hence one degree of freedom was lost for each year of observations, and one for each industry in each year in the cross sections within industries.

Industry regressions are based on means of all of the observations included in the cross sections for each industry-year. There are 10 "industries" in all, but in a number of cases failure to direct certain questions to an industry resulted in eliminating all of its observations for one or more years. Industry-year observations were in each case weighted by the number of individual firm observations. The various regressions therefore involve several partitionings of the overall sum of

⁴ Firm overall regressions will, in some cases, relate to time series observations only and thus match the sums of squares of deviations of time series observations and observations based on cross sections of firm means.

DEFINITIONS AND SOURCES OF VARIABLES AND INTERVALS FOR ACCEPTABLE VALUES

| Variable ^a | Symbols and Definitions | Source ^b | Acceptable Interval ^c |
|---|---|---------------------|----------------------------------|
| Capital Expenditures as Ratio of Gross Fixed Assets | $i_t = \frac{I_t}{K_{57}}$ | MH/FD | [.6,0] |
| | $i_t^* = \frac{I_t}{K_{t-1}}$ | MH/FD | [.6,0] |
| Capital Expenditure Anticipations as Ratio of Gross Fixed Assets | $i_{t+1}^t = \frac{I_{t+1}^t}{K_{57}}$ | MH/FD | [.6,0] |
| Capital Expenditures as Ratio of Price Deflated Gross Fixed Assets ^a | $i_{pt}^* = \frac{I_t}{K_{p,t-1}}$ | MH/FD | [.6,0] |
| Relative Sales Change Ratio | $\Delta s_t = \frac{3(S_t - S_{t-1})}{S_{56} + S_{57} + S_{58}}$ | FD | [.7, -.6] |
| | $\Delta s_t^* = \frac{3(S_t - S_{t-1})}{S_t + S_{t-1} + S_{t-2}}$ | FD | [.7, -.6] |
| Net Profits as Ratio of Gross Fixed Assets | $p_t = \frac{P_t}{K_{57}}$ | FD | [.7, -.4] |
| | $p_t^* = \frac{P_t}{K_{t-1}}$ | FD | [.7, -.4] |
| Net Profits as Ratio of Price-Deflated Gross Fixed Assets ^a | $p_{pt} = \frac{P_t}{K_{p,t-1}}$ | FD | [.7, -.4] |
| 1953 Depreciation Charges as Ratio of 1953 Gross Fixed Assets | $d_{53} = \frac{D_{53}}{K_{53}}$ | FD | [.2,0] |
| Expected Relative Sales Change Over Next Four Years | $\Delta s_{t+4}^t = \frac{S_{t+4}^t - S_t}{S_t}$ | MH | [1, -.4] |
| Expected Relative Sales Change Over Next Year | $\Delta s_{t+1}^t = \frac{S_{t+1}^t - S_t}{S_t}$ | MH | [.7, -.6] |
| Ratio of Actual to Preferred Rate of Utilization of Capacity | $uc_t^r = \frac{UC_t}{UC_t^o}$ | MH | [1.3,.3] |

DEFINITIONS AND SOURCES OF VARIABLES AND INTERVALS FOR ACCEPTABLE VALUES

| Variable ^a | Symbols and Definitions | Source ^b | Acceptable Interval ^c |
|--|--|---------------------|----------------------------------|
| Market Value of Firm=Sum of End-of-Year Bonded Indebtedness and Market Value of Common and Preferred Stock | $V_t = H_t + E_t$ | FD | — |
| Rate of Return = (Net Profits + Depreciation Charges + Interest Payments) ÷ Market Value of Firm | $r_t = \frac{P_t + D_t + B_t}{V_t}$ | FD | [.7, -.4] |
| Ratio of Market Value of Firm to Net Worth+Depreciation Reserve +Bonded Indebtedness | $m_t = \frac{V_t}{NW_t + R_t + H_t}$ | FD | [5,.1] |
| Relative Change in Market Value of Firm | $\Delta v_t = \frac{V_t - V_{t-1}}{V_{t-1}}$ | FD | [1.5, -.75] |
| Time Trend Integer, Beginning with Zero for First Year of Dependent Variable | T | — | [7,0] |

^a All flow variables (I , I'_{t+1} , S and P) except depreciation charges (D) and rate of return (r) are price deflated. No stock variables are price deflated except gross fixed assets (K_p), where indicated by a p subscript. Deflation procedures for flow variables are described in [3], pp. 141-142. Where price deflated values of gross fixed assets were used they were calculated as the sum of the previous five years of deflated capital expenditures plus an estimate of the deflated value of gross fixed assets not acquired in these five years. Thus,

$$K_{pt} = \sum_{j=0}^4 I_{p,t-j} + \frac{K_t - \sum_{j=0}^4 I_{t-j}}{\frac{1}{M} \sum_{h=1}^M P'_{t-h-4}},$$

where P' is a price deflator, p as a subscript denotes a price deflated variable and M is the lesser of an estimate of the firm's length of life of capital

$$\left(\frac{1}{D_{63}/K_{63}} \right)$$

and the number of years remaining back to 1946. (All gross fixed assets acquired prior to 1946 were thus arbitrarily assigned the post-1945 mean price deflator calculated above.

^b MH=McGraw-Hill surveys.

FD=Financial data, generally from Moody's.

MH/FD= Numerator from McGraw-Hill and denominator from financial data.

^c $[U, L]$ = Closed interval, including upper and lower bounds.

$[U, L)$ =Interval including upper bound but not lower bound.

squares and cross products: firm time series plus cross section of firm means equal firm overall (time series observations only); firm cross section within industries plus industry cross section equal firm cross section across industries; and firm cross section within industries plus industry overall equal firm overall.

IV. *The Findings*

Let us note first in Table 1 some of the broad outlines of the results. Looking at the firm-overall regression, pooling all observations for all industries for the eight years from 1955 to 1962, we can find once more a distributed lag accelerator. The sum of the sales change coefficients of .417 suggests that an increase in sales will bring about a substantial but less than proportionate increase in capital stock if a sufficiently long period, in this case six years, is allowed for firms to recognize the increase as permanent and to formulate and carry out appropriate plans to adjust their capital stock.

In the present work we have introduced current and lagged profits and met the resulting problem of multicollinearity by calculating the standard error of the sum of the two profits coefficients. The sum of only .053 in the firm-overall regression suggests that little more than 5 per cent of extra profit results in capital expenditures, other things remaining the same. With all of 3,147 observations, standard errors are small and each of the sales change coefficients as well as the sum of the profits coefficients clearly differs significantly from zero in a statistical sense. The curiously negative coefficient for current profits defies immediate explanation. Perhaps higher current capital expenditures cause higher current depreciation charges and higher current interest payments, and also entail "start-up" or other costs, all reducing current net profits.

It may also be noted that the ratio of 1953 depreciation to 1953 fixed assets, a measure of (the reciprocal of) length of life of capital and hence of replacement requirements, has a substantial, positive coefficient. One might infer that "replacement investment," as a ratio of 1957 gross fixed assets, is equal on the average to the constant term of .023, plus .053 times the mean of profits, .097, plus .763 times the mean of depreciation, .053. This comes to .069, which is 81 per cent of the mean capital expenditure ratio of .085.

So far, we are largely confirming earlier findings with a lesser body of data. Let us now note, also in Table 1, the contrast between results of the cross section of firms across industries and the cross section of firms within industries. By our hypothesis that firms may view differences between their own sales experience and that of other firms within their industry as less "permanent" than differences between

their own sales experience (or that of their industry) and the experience of all other firms, we should expect the sum of the coefficients of sales changes to be less in the case of the within-industry regression. And so it is: .361, as against .410 in the firm cross section across industries. Correspondingly, the sum of coefficients of sales changes in the industry cross section equals .533, consistent with our hypothesis that differences between industries would reflect in larger part differences in the permanent component of changes in demand. The within-industry profits coefficients are somewhat higher than those across industries, suggesting perhaps that firms do tend to invest their transitory increases in profits the year after they are received. Corresponding to these somewhat higher coefficients of lagged profits in the

regression for individual firms within industries, however, there is to be noted a sum of profits coefficients which is significantly negative in the industry cross section. Indeed the difference between the sums of profits coefficients in these latter regressions is .283, with a standard error of .077, quite significantly different from zero.

Turning now to the firm time series results in Table 2, we note first that the accelerator effect is less marked. While sales change coefficients are positive for each lagged sales change and quite significantly so for all except the last, the sum of the coefficients of .244 is decidedly less than the corresponding sum of .629 in the cross section of firm means shown in Table 2. The F -ratio of 5.44 for the reduction of residual variance confirms the heterogeneity of the regressions; the difference of .385 in the sums of coefficients, with a standard error of .071, is clearly statistically significant. This result is consistent with our hypothesis that firms would view variations in their own sales experience over a relatively short period of time (the eight years from

1955 to 1962, in this regression) as in lesser part permanent than the differences between their own average sales experience and the average experience of all other firms in the economy. To the extent that variation over time of their own sales experience is part of the variation over time of the experience of the industry as a whole, it may be viewed in larger part as permanent. Confirmation of this is suggested (in Table 1) by the sum of .477 for the coefficients of sales changes in the industry time series, larger than that in the firm time series (Table 2) although still smaller than that of the cross section of firm means.

The depreciation variable, as we have defined it, is a constant for each firm, and virtually a constant for each industry (differing from year to year in a given industry only with differences in the identities of firms in the industry sample); hence it was excluded from the time series regressions. As a consequence, higher profits coefficients in the time series relations may have reflected some of the role of replacement investment which is postponed until a year when profits are relatively higher. It may be added that introduction of a time trend variable, in those regressions where time varied, produced no appreciable change in either the regression coefficients or the constant term. The coefficient of the time trend variable was itself virtually zero.

One may wonder more about the role of our depreciation variable. It is instructive therefore to examine further Table 2, in which the depreciation variable has been deleted from the cross section regressions. We then note that the coefficients of sales changes and profits are somewhat higher. A possible explanation is that the 1953 ratio of depreciation to fixed assets was higher in more rapidly growing firms; perhaps, depreciation ratios were higher for firms which had invested heavily in the years immediately leading up to 1953 and firms investing heavily in those years were firms which continued to grow and invest heavily in future years. In any event, with the exclusion of the depreciation variable the sum of .950 for the coefficients of the sales changes in the industry cross section is comfortably close to the value of unity hypothesized by the writer in earlier work as appropriate under a certain set of assumptions (which include among others, sales changes dominated by permanent components, a production function homogeneous of the first degree, and the lack of effective ceilings or floors to investment); the F -ratio of 9.35 for the differences of regressions and the standard error of .170 for the excess of .527 over the within-industry sum of sales change coefficients of .422 clearly suggest statistical significance in the decomposition of cross section deviations.

Table 3 indicates that capital expenditure anticipations, in the main, are explained by the same factors as capital expenditures themselves. A perhaps conspicuous difference is to be found in the firm time series,

TABLE 3—CAPITAL EXPENDITURE ANTICIPATIONS, 1955-62, AS A FUNCTION OF SALES CHANGES, PROFITS AND DEPRECIATION:
FIRM AND INDUSTRY TIME SERIES, CROSS SECTION AND OVERALL REGRESSIONS

where the sum of the coefficients of sales changes is only .090, as against .244 in the regressions of actual capital expenditures, while the sum of profits coefficients equals .261 for anticipations as against .179 for actual capital expenditures. May this not be interpreted as a partial confirmation of the existence of a business myth regarding the relative roles of profits and demand? The relation between profits and what businesses *say* they will invest the following year is a better one than that between profits and what they actually do invest.⁵ Their actual investment, even merely the timing of it, is influenced more by sales changes, which are apparently almost ignored in statements of capital expenditure anticipations.

The anticipations relation shown in Table 3 also brings into sharper focus a difference in the roles of profits in the time series and cross section which might have been noticed less distinctly in Table 2 with regard to actual capital expenditures. For the sum of profits coefficients of .261 in the firm time series exceeds the sum of .120 in the cross section of means by the amount of .141, more than three times the standard error of .044 for that difference. The greater covariance of anticipated capital expenditures and profits over time than between firms suggests that profits may have a greater role in the timing of capital expenditures than in determining their total amount.

Table 4, dealing with only the years 1960 through 1962, differs from the earlier tables in the addition of variables measuring the rate of return as a ratio of the market value of the firm (r) and the ratio of the market value of the firm to the sum of net worth, depreciation reserves, and bonded indebtedness (m). Both of these additional variables were introduced in current and lagged form, with sums and standard errors of sums of coefficients of the current and lagged variables again presented to get around problems of multicollinearity. Results, however, are somewhat disappointing. Thus, it might have been expected that the value-of-the-firm ratio (m) would be positively associated with capital expenditures, but this is not confirmed in the coefficients for any of the individual firm regressions and the number of observations was insufficient in the industry regressions to warrant their presentation.⁶

⁵ The difference cannot be explained by differences in the relative lags from *current* actual capital expenditures and anticipations relating to *next year*. For with comparable deletions of sales change and profits variables, the coefficients of similarly lagged profits are, for expenditures and anticipations, respectively, .189 and .272, with a standard error of the difference just under .04.

⁶ The value-of-the-firm ratio might appear conceptually better if the depreciation reserve were netted out of the denominator, which denotes essentially the *accounting* value of the firm. It may be doubted, however, whether this change would significantly affect the results, particularly in view of the dubious quality of the relation between accounting and economic depreciation.

^a F -ratio for differences of regressions of firm time series and cross sections of firm means was 1.52 (14, 591), not significant at the .05 probability level, and hence no differences of coefficients are presented.

With regard to the variables measuring rate of return (r), it was thought that in a regression already including profits, their coefficients would prove negative. For when profit expectations are higher than

current profits, the value of the firm would be relatively higher, and the current rate of return lower, while with generally high profit expectations, the marginal efficiency of investment would probably be greater and capital expenditures higher. Some support for this chain of reasoning may be noted in the time series results, where the sum of the coefficients of rates of return is indeed negative and significantly so.

We may recall that the variable measuring rates of return includes depreciation charges in the numerator and that time series variation in depreciation involves, at least in part, changes stemming from application of the accelerated depreciation provisions of the Internal Revenue Act of 1954. The negative time series coefficients of "rates of return" would thus appear also to imply a contradiction of the sometimes asserted argument that higher depreciation charges, *per se*, bring about higher rates of investment. On the other hand, however, the rate of return variable, which includes interest payments in the numerator, may be taken as a measure, although imperfect, of the cost of capital. It may then be argued that its negative coefficient reflects the expected negative relation between capital expenditures and the cost of capital.

Tables 5 and 6 are comparable to Tables 1 and 2, except that capital expenditures and profits are now deflated by the previous year's capital stock rather than capital stock of 1957, and sales changes are deflated by a three-year moving average of lagged sales rather than the average sales centered on 1957. The formulation underlying the earlier tables has certain advantages in easy interpretation and comparison of coefficients of successively lagged terms. Some deflator is necessary to eliminate heteroscedasticity associated with heterogeneity in size of firm. When all sales changes are deflated by average sales of a given period, equal values of sales-change variables of different years reflect equal changes in physical volume of sales. Coefficients relating to different lags are hence directly comparable. Deflating capital expenditures by capital stock of the period corresponding to that of the sales average then permits direct inference about a sum of coefficients of successive sales changes.

Since using this technique of deflation in previous work, however, I have felt some qualms. These concern the possibility that, despite continuing efforts to eliminate from our sample firms that have merged or made major acquisitions in the period under analysis, this use of a deflator of some given past year creates increasing havoc. For if included firms are growing by acquisitions or mergers, both capital expenditures and (generally rising) sales would in later years appear to be higher ratios of 1957 capital stock and sales, respectively. Thus for firms growing by the merger or acquisition route the variables measuring capital expenditures, sales changes (and profits) would all be

TABLE 5—CAPITAL EXPENDITURES, 1955–1962, AS A FUNCTION OF SALES CHANGES, PROFITS, AND DEPRECIATION, ALL EXCEPT DEPRECIATION MEASURED AS RATIOS OF PREVIOUS YEAR'S GROSS FIXED ASSETS OR PREVIOUS THREE YEAR SALES AVERAGE: FIRM AND INDUSTRY TIME SERIES, CROSS SECTION AND OVERALL REGRESSIONS

higher than for firms not growing in this fashion, merely because of our out-of-date deflators. This would suggest that my earlier findings in support of the accelerator relation might be at least in part spurious.

To test this distributing possibility, variables were redefined as indicated in the regressions reported upon in Tables 5 and 6, as well as subsequent tables. I am indeed happy to report that the results are essentially undisturbed.⁷

One marked departure which we may note in Table 5 is the decidedly positive coefficient of the current profit variable in the firm time se-

⁷ The somewhat smaller sample in Tables 5 and 6 is caused chiefly by the loss of observations for which sales information was available for 1956, 1957, 1958 but not always for other years. In particular, lack of earlier sales information would eliminate observations because of the absence of lagged sales for the denominator of the last lagged sales change variable.

TABLE 6—CAPITAL EXPENDITURES, 1955-62, AS A FUNCTION OF SALES CHANGES AND PROFITS, MEASURED AS RATIOS OF PREVIOUS YEAR'S GROSS FIXED ASSETS OR PREVIOUS THREE-YEAR SALES AVERAGE: FIRM AND INDUSTRY CROSS SECTIONS AND FIRM TIME SERIES AND OVERALL REGRESSIONS

ries regression. The sum of the profit coefficients here is a rather astonishingly large .563 and, correspondingly, .491 in the industry time series. This serves to underscore our earlier inference, from the contrast of time series and cross section results observed in examining Table 3, that profits may have a role in determining the timing of investment rather than its average rate over time.

Table 7 enables us to explore the role of expected sales changes in regressions for all of the years 1955-1962. Although the number of observations is markedly reduced because of missing information on expected sales changes, we still have 1,465 individual firm observations and 60 industry-year-mean observations. We now observe some positive association between expected sales changes, particularly those over the longer-run four-year period, and capital expenditures. It would appear that past sales changes may be a proxy for the relation between expected future demand and capacity but that expected sales changes over a four-year period, as reported by McGraw-Hill respondents, offer further information bearing on long-run or permanent sales. The suggestion seems strongest in firm time series where the introduction of sales expectations increases the sum of all coefficients of sales changes from .276 in Table 5 to .346 in Table 7, and in within-industry firm cross sections where it increases the sum of all coefficients of sales changes from .287 to .342. This is consistent with our hypothesis that relatively more of the variance of past sales changes within firms

and within industries is viewed as transitory. The variance of sales expectations would then prove a net addition to the permanent component of sales variance.⁸

Since questions soliciting the information used in constructing the utilization-of-capacity variable, uc^r , were not included in all McGraw-Hill surveys, the Table 8 regressions introducing uc^r are based on 1955, 1957, 1960, and 1962 observations only. The results would appear to confirm a small but distinctly positive role for this direct measure of the pressure of output upon capacity.

Table 9, for the years 1961 and 1962 only, introduces Δv , measuring the change in value of the firm. It indicates that, even given past sales changes, the rate of investment tends to be greater in those firms that have seen greater increases (or lesser decreases) in the market's evaluation of the firm both for the current year and the past year. The Δv variable, however, seems essentially to be picking up effects attributed to corresponding Δs variables when Δv is not included. This suggests that, at least insofar as investment is con-

⁸ It is also possible, however, that we are really measuring the relation between capacity-expanding investment and the sales increases these are expected to make possible rather than any role of sales anticipations in determining investment.

cerned, "the market" did little more than project current sales changes. The sum of the Δv coefficients was somewhat larger in the cross section of firm means and largest in the industry cross section, amounting there to .232, with a standard error of .065. One may infer that the transitory, year-to-year variation of market value of individual firms tends to bias downward our estimates of these coefficients.

Finally, in Table 10, we present results with price-deflated gross fixed assets as the divisor of capital expenditures and profit. The results are not found to differ sharply from those shown in Tables 5 and 6, where gross fixed assets were not price deflated; the sum of sales change coefficients is slightly higher and that of profit coefficients slightly lower in the individual firm cross sections. The sample is

somewhat different and considerably smaller, however, as our method of capital stock deflation eliminated observations for which information as to five successive years of capital expenditures was not available. Other differences in coefficients seem fairly well within the range of sampling variability.

V. Summary and Conclusions

Taking time series and cross section slices of the same body of data at the levels of the firm and of broad industry groups, we have noted significant differences in estimates of the factors affecting capital expenditures and have tried to relate them to differing permanent and transitory components in the relevant variances and covariances. Our main findings are as follows:

1. The role of past sales changes, presumably as a proxy for expected long-run pressure of demand on capacity, appears greatest in the case of industry cross sections, and large in cross sections of firms across industries, particularly in cross sections of firm means.

2. The coefficients of past sales changes are correspondingly lower in the within-industry cross sections.

3. The variance of past sales changes about the mean of sales changes for each individual firm (firm time series) has significantly less to do with the variance in capital expenditures than the corresponding variances in the firm cross sections. This is consistent with the view that firms would look upon the short-run variance in their own sales as mostly transitory.

4. Coefficients of sales changes are generally higher in industry time series than in firm time series. This is consistent with the hypothesis of a greater permanent component in industry sales change variance over time.

5. New light is cast on the role of profits in distributed lag investment functions including a considerable number of lagged sales changes. While coefficients of the profit variables are uniformly low in cross sections they are relatively high in most of the time series. Firms apparently tend to make capital expenditures in the period immediately following higher profits, but firms earning higher profits do not make markedly greater capital expenditures than firms earning lower profits. This evidence is consistent with the hypothesis that past profits play some significant role in the timing of capital expenditures but do not affect its long-run average.

6. Expected sales changes may have some role in capital expenditures over and above that noted in current and lagged actual sales changes. The sales change expected over the ensuing four-year period, in particular, is positively related to capital expenditures.

7. The rate of return on market value of the firm does not prove statistically significant in the cross sections but its coefficient is distinctly negative in the firm time series. One may presume that expected future earnings are positively related to the expected profitability of investment, and hence to investment itself, as well as to the value of the firm. Given current profits, the observed negative relation between capital expenditures and rate of return could then be attributed to fluctuations in expected earnings. This is consistent with the general hypothesis that expected future earnings (long-run or permanent income) play an underlying role in the investment function. Some confirmation may be found in positive coefficients of variables measuring changes in the value of the firm, but none in estimates of coefficients of the ratio of the market value of the firm to a "book value" constructed as the sum of net worth, depreciation reserves, and bonded indebtedness.

8. Further evidence of the role in capital expenditures of the pressure of demand on capacity appears in positive coefficients of the ratios of actual to preferred rates of utilization of capacity.

9. Results do not differ markedly when capital expenditures and profits are divided by price-deflated gross fixed assets rather than gross fixed assets at original cost.

All of this should be taken as a preliminary report of intensive investigation of a large and greatly expanded body of individual firm data. It does confirm, however, that wide differences, far beyond those which may reasonably be expected from sampling variability, can appear in estimates of economic relations from the same underlying data when observations are grouped in different ways. The differences in estimates, in the context of the investment function, as in the consumption function, may plausibly be related to differences in the "permanent" components of the variables under consideration. To the extent that our econometric efforts are intended to reveal structural relations rather than to be merely descriptive of particular arrangements of data, it would appear vitally important to define the parameters to be estimated clearly in terms of the nature of the variances to which they are to apply.

APPENDIX A

CLASSIFICATION OF OBSERVATIONS USED IN TABLES 1, 2, AND 3, BY INDUSTRY AND YEAR

| Industry | Number of Observations | | | | | | | | |
|---|------------------------|------|------|------|------|------|------|------|-------|
| | 1955 | 1956 | 1957 | 1958 | 1959 | 1960 | 1961 | 1962 | Total |
| Primary metals | 22 | 31 | 25 | 27 | 25 | 26 | 24 | 26 | 206 |
| Metal working | 102 | 131 | 109 | 96 | 87 | 96 | 90 | 84 | 795 |
| Chemical processing | 64 | 73 | 69 | 58 | 58 | 65 | 56 | 49 | 492 |
| All other manufacturing | 64 | 88 | 78 | 66 | 60 | 62 | 55 | 54 | 527 |
| Mining | 9 | 15 | 12 | 10 | 7 | 12 | 10 | 11 | 86 |

| Railroads | 25 | 27 | 26 | 24 | 21 | 20 | 17 | 13 | 173 |
| Transportation and communication other than railroads | 7 | 10 | 13 | 12 | 12 | 9 | 11 | 11 | 85 |
| All industries | 386 | 492 | 439 | 397 | 369 | 383 | 353 | 328 | 3,147 |

APPENDIX B: ALGEBRAIC STATEMENT OF DEVIATIONS USED
IN THE VARIOUS REGRESSIONS

Let X_{fnt} denote the observation vector of firm f in industry n for the year t .

Let F_{nt} denote the number of firms with observations in industry n for the year t .

Let τ_{fn} denote the number of years of observations for firm f in industry n .

Let N_t denote the number of industries containing observations in the year t .

Let τ denote the number of years for which observations are available. Then,

$$\bar{X}_{fn} = \frac{\sum_{t=1}^{\tau_{fn}} X_{fnt}}{\tau_{fn}} = \text{the mean of observations of all years for firm } f \text{ in industry } n \text{ (firm mean),}$$

$$\bar{X}_{nt} = \frac{\sum_{f=1}^{F_{nt}} X_{fnt}}{F_{nt}} = \text{the mean of observations of all firms in industry } n \text{ in year } t \text{ (industry-year mean),}$$

$$\bar{X}_n = \frac{\sum_{t=1}^{\tau} \sum_{f=1}^{F_{nt}} X_{fnt}}{\sum_{t=1}^{\tau} F_{nt}} = \begin{array}{l} \text{the mean of observations of all firms in industry } n, \\ \text{in all years (industry mean),} \end{array}$$

$$\bar{X}_t = \frac{\sum_{n=1}^{N_t} \sum_{f=1}^{F_{nt}} X_{fnt}}{\sum_{n=1}^{N_t} F_{nt}} = \begin{array}{l} \text{the mean of observations of all firms in all in-} \\ \text{dustries in year } t \text{ (year mean), and} \end{array}$$

$$\bar{X} = \frac{\sum_{t=1}^{\tau} \sum_{n=1}^{N_t} \sum_{f=1}^{F_{nt}} X_{fnt}}{\sum_{t=1}^{\tau} \sum_{n=1}^{N_t} F_{nt}} = \begin{array}{l} \text{the mean of all observations of all industries in} \\ \text{all years (overall mean).} \end{array}$$

Hence,

$X_{fnt} - \bar{X}_{fn}$ = the deviations used in firm time series and

$\bar{X}_{fn} - \bar{X}$ (weighted by τ_{fn}) = the deviations used in the cross sections of firm means, each variable relating only to observations from firms for which $\tau_{fn} > 1$,

$X_{fnt} - \bar{X}_{nt}$ = the deviations used in firm cross sections within industries,

$X_{fnt} - \bar{X}_t$ = the deviations used in firm cross sections across industries, and

$X_{fnt} - \bar{X}$ = the deviations used in firm overall regressions.

Finally,

$\bar{X}_{nt} - \bar{X}_n$ = the deviations used in industry time series.

$\bar{X}_{nt} - \bar{X}_t$ = the deviations used in industry cross sections,

$\bar{X}_{nt} - \bar{X}$ = the deviations used in industry overall regressions, and

$$\frac{F_{nt} \sum_{t=1}^{\tau} N_t}{\sum_{t=1}^{\tau} \sum_{n=1}^{N_t} F_{nt}} = \begin{array}{l} \text{the weight attached to the observation for industry } n \text{ in the} \\ \text{year } t. \end{array}$$

TAX POLICY AND INVESTMENT BEHAVIOR

By ROBERT E. HALL AND DALE W. JORGENSEN*

The effectiveness of tax policy in altering investment behavior is an article of faith among both policy makers and economists. Whatever the grounds for this belief, its influence on postwar tax policy in the United States has been enormous. In 1954 and again in 1962 amortization of capital expenditures was liberalized by providing for faster writeoffs. Since 1962 a tax credit for expenditure on equipment has been in force. Nor is tax policy in the United States atypical. As Otto Eckstein [8] has pointed out,

Tax devices to stimulate investment have certainly been the greatest fad in economic policy in the past ten years. In a period when the trends in the use of policy instruments were in the direction of more general, less selective devices, all sorts of liberalized depreciation schemes, investment allowances, and tax exemptions were embraced with enthusiasm all over the non-Communist world.¹

The customary justification for the belief in the efficacy of tax stimulus does not rely on empirical evidence. Rather, the belief is based on the plausible argument that businessmen in pursuit of gain will find the purchase of capital goods more attractive if they cost less.² In view of the policy implications of this theoretical argument, it is surprising that no attempt has been made to estimate the magnitude of tax effects on investment. Previous studies have been limited to calculations of the effects of tax policy on the cost of capital services.³ The relation between these changes in the cost of capital and actual investment expenditures has not been studied empirically. As a result, the most important questions for economic policy—How much investment will result from a given policy measure? When will it occur?—have been left unanswered.

The purpose of this paper is to study the relationship between tax policy and investment expenditures using the neoclassical theory of

* Robert E. Hall is a graduate student at Massachusetts Institute of Technology and Dale W. Jorgenson is professor of economics at the University of California, Berkeley. Funds for the research done in this paper were provided by a National Science Foundation grant through the Institute of Business and Economic Research at the University of California, Berkeley.

¹ See [8, p. 351]; an excellent comparison of U.S. and European tax policy, including depreciation policy and investment tax credits, is given in [7].

² The effects of tax policy on investment behavior are analyzed from this point of view by N. B. Ture [19, esp. pp. 341-45]; by S. B. Chase, Jr. [3]; and by R. A. Musgrave [15, pp. 53-54, 117-29]. Many other references could be given.

optimal capital accumulation.⁴ First, we measure the cost to the business firm of employing fixed assets. This cost depends on the rate of return, the price of investment goods, and the tax treatment of business income. Second, we determine empirically the relation between the cost of employing capital equipment and the level of investment expenditures. This relationship is a straightforward generalization of the familiar flexible accelerator theory of investment. We first obtain an estimate of the distribution over time of the investment expenditures resulting from a given increment in the desired level of capital services; then we estimate both the amount of investment resulting from a change in tax policy and its distribution over time. We consider the effects of: (1) the adoption of accelerated methods for computing depreciation for tax purposes in 1954, (2) the investment tax credit of 1962, and (3) the depreciation guidelines of 1962. As an illustration we consider the hypothetical effects of (4) adoption of first-year writeoff in 1954 in place of less drastic accelerated depreciation.

Our basic conclusion is that tax policy is highly effective in changing the level and timing of investment expenditures. In addition we find that tax policy has had important effects on the composition of investment. According to our estimates, the liberalization of depreciation rules in 1954 resulted in a substantial shift from equipment to structures. On the other hand, the investment tax credit and depreciation guidelines of 1962 caused a shift toward equipment.

I. Tax Policy and the Cost of Capital Services

The neoclassical theory of optimal capital accumulation may be formulated in two alternative and equivalent ways. First, the firm may be treated as accumulating assets in order to supply capital services to itself. The objective of the firm is to maximize its value, subject to its technology. Alternatively, the firm may be treated as renting assets in order to obtain capital services; the firm may rent assets from itself or from another firm. In this case, the objective of the firm is to maximize its current profit, defined as gross revenue less the cost of current inputs and less the rental value of capital inputs. The rental can be calculated from the basic relationship between the price of a new capital good and the discounted value of all the future services derived from this capital good.⁵ In the absence of direct taxation this relationship takes the form:

$$(1) \quad q(t) = \int_t^{\infty} e^{-r(s-t)} c(s) e^{-\delta(s-t)} ds,$$

where r is the discount rate, q the price of capital goods, c the cost of

⁴ This model has been studied previously by D. W. Jorgenson [11 and 12].

⁵ The equivalence of these two formulations is discussed by D. W. Jorgenson [14].

capital services, and δ the rate of replacement; in this formulation t is the time of acquisition of the capital goods and s the time at which capital services are supplied. Differentiating this relationship with respect to time of acquisition we obtain:

$$(2) \quad c = q(r + \delta) - \dot{q},$$

which is the rental of capital services supplied by the firm to itself. Under static expectations about the price of investment goods, the rental reduces to:

$$(3) \quad c = q(r + \delta).$$

Expression (3) derived above for the cost of capital services may be extended to take account of a proportional tax on business income. We assume that the tax authorities prescribe a depreciation formula $D(s)$ which gives the proportion of the original cost of an asset of age s that may be deducted from income for tax purposes. Further, we assume that a tax credit at rate k is allowed on investment expenditure and that the depreciation base is reduced by the amount of tax credit.⁶ If the tax rate is constant over time at rate u , the equality between the price of investment goods and the discounted value of capital services is:

$$(4) \quad q(t) = \int_t^{\infty} e^{-r(s-t)} [(1-u)c(s)e^{-\delta(s-t)} + u(1-k)q(t)D(s)]ds + kq(t).$$

Denoting by z the present value of the depreciation deduction on one dollar's investment (after the tax credit),

$$(5) \quad z = \int_0^{\infty} e^{-rs} D(s) ds.$$

The implicit rental value of capital services under static expectations then becomes:

$$(6) \quad c = q(r + \delta) \frac{(1-k)(1-uz)}{1-u}$$

Under the Internal Revenue Code of 1954 at least three depreciation formulas could be employed for tax purposes: straight-line, sum of the years' digits, and double declining balance. To obtain the appropriate cost of capital services for each formula, it is necessary to calculate the present value of the depreciation deduction for each one. Throughout we assume that the asset has no salvage value.

For straight-line depreciation, the deduction is constant over a period of length τ , the lifetime for tax purposes:

⁶ This assumption is valid for 1962 and 1963. For 1964 and later years the depreciation base was not reduced by the amount of the tax credit.

$$D(s) = \begin{cases} \frac{1}{\tau} & \text{for } 0 \leq s \leq \tau, \\ 0 & \text{otherwise.} \end{cases}$$

The present value of the deduction is:

$$\begin{aligned} z &= \int_0^{\tau} \frac{e^{-rs}}{\tau} ds, \\ (7) \quad &= \frac{1}{r\tau} (1 - e^{-r\tau}). \end{aligned}$$

For sum of the years' digits, the deduction declines linearly over the lifetime for tax purposes:

$$D(s) = \begin{cases} \frac{2(\tau - s)}{\tau^2} & \text{for } 0 \leq s \leq \tau, \\ 0 & \text{otherwise.} \end{cases}$$

The present value of the deduction is:

$$\begin{aligned} z &= \int_0^{\tau} e^{-rs} \frac{2(\tau - s)}{\tau^2} ds, \\ (8) \quad &= \frac{2}{r\tau} \left[1 - \frac{1}{r\tau} (1 - e^{-r\tau}) \right]. \end{aligned}$$

Tax provisions for double declining balance depreciation are more complicated. A firm may switch to straight-line depreciation at any time. If the switchover point is denoted τ^+ , the double declining balance depreciation formula is:

$$D(s) = \begin{cases} \frac{2}{\tau} e^{-(2/\tau)s} & \text{for } 0 \leq s \leq \tau^+, \\ \frac{1 - e^{-(2/\tau)\tau^+}}{\tau - \tau^+} & \text{for } \tau^+ \leq s \leq \tau \\ 0 & \text{otherwise.} \end{cases}$$

The present value of the deduction is:

$$\begin{aligned} z &= \frac{2}{\tau} \int_0^{\tau^+} e^{-(r+(2/\tau))s} ds + \frac{1 - e^{-(2/\tau)\tau^+}}{\tau - \tau^+} \int_{\tau^+}^{\tau} e^{-rs} ds, \\ (9) \quad &= \frac{\frac{2}{\tau}}{r + \frac{2}{\tau}} [1 - e^{-(r+(2/\tau))\tau^+}] + \frac{1 - e^{-(2/\tau)\tau^+}}{r(\tau - \tau^+)} (e^{-r\tau^+} - e^{-r\tau}). \end{aligned}$$

The switchover point which maximizes z is $\tau^+ = \tau/2$.

Representative values of the present value of the deduction for each of the three methods are given in Table 1.⁷ From this table it is clear that the sum of the years' digits depreciation formula dominates the double declining balance and straight-line formulas in the range of discount rates and lifetimes with which we are concerned. For this reason we have represented the 1954 tax revision as a change from straight-line to sum of the years' digits depreciation formulas.⁸ Under static expecta-

TABLE 1—PRESENT VALUE OF DEPRECIATION DEDUCTION

| Lifetime | Interest Rate | Straight-line | Sum of the Years' Digits | Double Declining Balance |
|----------|---------------|---------------|--------------------------|--------------------------|
| 5 | .06 | .864 | .907 | .888 |
| 5 | .12 | .752 | .827 | .795 |
| 10 | .06 | .752 | .827 | .795 |
| 10 | .12 | .582 | .696 | .651 |
| 25 | .06 | .518 | .643 | .594 |
| 25 | .12 | .317 | .456 | .410 |
| 40 | .06 | .379 | .518 | .469 |
| 40 | .12 | .207 | .331 | .297 |

tions the formulas for the rental value of capital services for these two methods of depreciation are:

straight-line:

$$(10) \quad c = \frac{1-k}{1-u} q(r+\delta) \left[1 - \frac{u}{r\tau} (1 - e^{-r\tau}) \right];$$

sum of the years' digits:

$$(11) \quad c = \frac{1-k}{1-u} q(r+\delta) \left[1 - u \frac{2}{r\tau} \left(1 - \frac{1}{r\tau} \{ 1 - e^{-r\tau} \} \right) \right].$$

Under the assumption that firms behave so as to maximize profit and that the markets for their output are perfectly competitive, a firm's

⁷ The results presented in Table I may be compared with those of Sidney Davidson and D. F. Drake [5]; see also: Davidson and Drake [6].

⁸ The adoption of accelerated methods for computing depreciation in 1954 involved a change from straight-line depreciation to either sum of the years' digits or double declining balance formulas. Since sum of the years' digits offers a slight advantage over double declining balance, we have assumed that accelerated depreciation was taken in the form of the sum of the years' digits. Further, we have assumed that accelerated methods were adopted immediately after they were made available. In fact, approximately 50 per cent (of new assets) were depreciated on an accelerated basis the first year and a similar percentage of the uncovered balance was added in subsequent years. For firms that had negotiated shorter lifetimes than those allowed beginning 1954, there was some incentive to continue using straight-line methods in order to meet the "reserve ratio test," now effectively abandoned. The shorter lifetimes may be approximated by accelerated depreciation.

desired level of capital can be derived from the condition that the value of the marginal product of capital should be equal to the rental price of capital. For a Cobb-Douglas production function, the desired level of capital K^+ is:

$$(12) \quad K^+ = \alpha \frac{pQ}{c},$$

where p is the price of output, Q its quantity, c the rental price of capital, and α the elasticity of output with respect to capital. We assume that the flow of capital services is proportional to capital stock. This completes the determination of desired capital.⁹

To complete the theory of investment behavior it is necessary to specify the relationship between changes in desired capital and actual investment expenditures. After a change in the desired level of assets, plans must be formulated, funds appropriated, orders and contracts let, and so on. We assume that subsequent to a change in desired capital, a certain proportion of the resulting investment expenditure takes place over each interval of time. This proportion may vary by class of asset but is independent of calendar time.¹⁰

Second, we must specify the theory of replacement investment. We assume that subsequent to an investment a certain proportion is replaced over each interval of time. Again, we allow this proportion to vary by class of asset, but assume it to be independent of calendar time. Under our earlier assumption of a constant rate of replacement, investment for replacement is proportional to capital stock. This assumption implies an exponential survival curve for capital goods.¹¹

Under these assumptions the theory of investment behavior takes the form of a distributed lag function; in discrete form this function may be written:

$$(13) \quad I_t = \sum_{s=0}^{\infty} \mu_s \Delta K_{t-s}^+ + \delta K_t.$$

Gross investment in period t , I_t , is the sum of a weighted average of past changes in desired capital and replacement investment. The change in desired capital in period $t-s$ is ΔK_{t-s}^+ ; the parameter μ_s is the proportion of the change in desired capital in period $t-s$ that results in investment expenditures in period t . Replacement investment is proportional to capital stock K_t ; the constant of proportionality is δ , the rate of replacement. An alternative and equivalent form of the distributed lag

⁹ A more detailed derivation of desired capital stock is given in "Anticipations and Investment Behavior," [11, pp. 43-53].

¹⁰ This theory of investment is discussed in more detail in "Anticipations and Investment Behavior," [11, pp. 46-50].

¹¹ See "Anticipations and Investment Behavior," [11, p. 51].

function gives net investment N_t as a weighted average of past changes in desired capital stock:

$$(14) \quad \begin{aligned} N_t &= I_t - \delta K_t, \\ &= \sum_{s=0}^{\infty} \mu_s \Delta K_{t-s}^+. \end{aligned}$$

To estimate the parameters of the distributed lag function, it is necessary to impose further restrictions on the sequence of coefficients $\{\mu_s\}$. We have taken the first two coefficients of this sequence to be arbitrary with the remaining coefficients declining in a geometric series. The final form of the resulting distributed lag function is:

$$(15) \quad N_t = \gamma_0 \Delta K_t^+ + \gamma_1 \Delta K_{t-1}^+ - \omega N_{t-1},$$

where γ_0 , γ_1 , and ω are parameters that characterize the sequence $\{\mu_s\}$. Adding an independently and identically distributed random term ϵ_t to the final form, we obtain the regression function:

$$(16) \quad N_t = \alpha \gamma_0 \Delta \frac{p_t Q_t}{c_t} + \alpha \gamma_1 \Delta \frac{p_{t-1} Q_{t-1}}{c_{t-1}} - \omega N_{t-1} + \epsilon_t,$$

where α is the elasticity of output with respect to capital. The parameters γ_0 , γ_1 , ω and α are unknown and must be estimated.¹² This investment function provides the basis for the statistical results reported in the following section.

To summarize, investment in period t depends on the capital stock at the beginning of the period and changes in the desired level of capital stock in previous periods. The form of the relationship depends on the parameters of the distributed lag function and the rate of replacement. Desired capital depends in turn on the value of output, the rental value of capital input, and the elasticity of output with respect to capital input.

The effects of tax policy on investment behavior enter the investment function through the rental value of capital input. A change in tax policy changes the rental value of capital input. This results in a change in the desired level of capital stock. A change in desired capital stock results in net investment (or disinvestment), bringing capital stock up (or down) to its new desired level. If there are no further changes in tax policy or in the other determinants of desired capital stock, net investment eventually drops to zero. The change in tax policy continues to affect gross investment through replacement of a permanently larger (or smaller) capital stock.

¹² Methods of estimation for such a distributed lag function are discussed by D. W. Jorgenson [13].

Our procedure is, first, to estimate the investment functions under the tax policies that actually prevailed. The results are given in the following section. Second, we employ the estimated investment functions to calculate the investment resulting from alternative tax policies. These calculations are given in Section III. We then analyze the results in order to assess the effectiveness of tax policy in changing the level and timing of investment expenditures. We also study the effects of tax policy on the distribution of investment between plant and equipment.

II. *Estimates of the Parameters of the Investment Function*

To implement the theory of investment behavior outlined in the preceding section, we have fitted the corresponding econometric model to data on investment expenditures from the Capital Goods Study of the Office of Business Economics (OBE).¹³ Data are available for structures and equipment separately and for both manufacturing and non-farm, non-manufacturing sectors of the U.S. economy for the years 1929–63. These data are derived by allocating the commodity flow data on gross private domestic investment from the national product accounts among sectors of destination.

Estimates of capital stock at the beginning of each period K_t , were obtained by applying the following recursion relation to the investment data described above:

$$(17) \quad K_t = I_{t-1} + \delta K_{t-1},$$

where I_t is investment in current prices deflated by an investment goods price index and δ is the rate of replacement, taken to be 2.5 times the inverse of the Bulletin F [21] lifetime. The following values were used for δ :

| | |
|--|--------|
| manufacturing equipment | 0.1471 |
| manufacturing structures | 0.0625 |
| non-farm, non-manufacturing equipment | 0.1923 |
| non-farm, non-manufacturing structures | 0.0694 |

Initial values for capital stock were estimated by cumulating net investment over the whole period for which data are available for each asset.

Published price indexes for gross private domestic investment are biased because to a considerable extent they measure the prices of inputs to the capital goods industries rather than the price of output. To overcome this bias, we used price indexes based on output prices that are close substitutes in production for producers' durables and business structures—the implicit deflator for consumers' durables from the national product accounts and the Bureau of Public Roads price index for

¹³ The OBE Capital Goods Study is reported by George Jaszi, Robert Wasson, and L. Grose [10]. More recent data were kindly supplied by Mr. Robert Wasson of the OBE.

structures.¹⁴ For the years before these indexes are available we used the indexes implicit in the OBE Capital Goods Study, adjusted for bias in the rate of growth. The biases were estimated by regression which yielded the following values: 0.00651 per year for equipment and 0.0183 per year for structures.

The effects of tax policy enter the investment function through the desired level of capital stock. To estimate the desired level we used value added at factor cost as a measure of output $p_t Q_t$. We calculated value added for manufacturing and non-manufacturing, non-farm sectors by adding estimates of capital consumption allowances to national income originating in each sector.¹⁵

The desired level of capital stock also depends on the rental value of capital input c_t . Through 1953 the appropriate rental value of capital services corresponds to straight-line depreciation. Since 1954 the appropriate rental value corresponds to sum of the years' digits depreciation. Until 1962 the investment tax credit k is equal to zero. For 1962 and 1963 this credit is 7 per cent of the value of investment goods. In the formulas for the rental value of capital goods, the tax rate u , the after-tax rate of return r , the investment goods price q , and the lifetime of capital goods allowable for tax purposes τ are variables. The rate of replacement δ is a fixed parameter. The values of this parameter are the same as those employed in calculating capital stock.

We took the corporate tax rate to be the statutory rate prevailing during most of the year. We did not attempt to allow for excess profits taxes during the middle thirties or the Korean War. For the discount

¹⁴ The implicit deflators for structures from the U.S. national accounts are primarily indexes of the cost of input rather than the price of output. The Bureau of Public Roads index for structures is based on the price of output; D. C. Dacy [4] has derived price indexes for road construction based on input and output prices. His index for the price of output grows from 80.5 to 98.2 from 1949 through 1959 while the price of input grows from 61.5 to 102.4 in the same period, both on a base of 100.0 in 1958. The implicit deflator for new construction in the national accounts grows from 51.3 to 103.0 in the same period. Although there is no real alternative to the Bureau of Public Roads index as an output price for structures, it is reassuring to find that the corresponding input price behaves in a manner very similar to that of the input price for all of new construction.

The price indexes for equipment from the U.S. national accounts are based on data from the wholesale price index of the Bureau of Labor Statistics. Since expenditures in the wholesale price index are less than those on the consumer's price index, adjustments for quality change are less frequent and less detailed. Some notion of the resulting bias in the growth of the implicit deflator for producers' durables can be obtained by comparing this index with the implicit deflator for consumers' durables. The producers' durables deflator increased from 64.6 in 1947 to 102.0 in 1959. Over this same period the deflator for consumers' durables increased from 82.7 to 101.4. Both indexes are computed relative to a base of 100.0 in 1958. A direct comparison of the durables components of the wholesale and consumers' price indexes reveals essentially the same relationship.

For further discussion, see Zvi Griliches and D. W. Jorgenson [9].

¹⁵ All data are from the U.S. national accounts; see: U.S. Dept. of Commerce [20] and *Survey of Current Business* [18].

rate before taxes we used the figure of .14 throughout the period. Although there is little evidence that this rate varies over the period of fit, except for cyclical fluctuations, this rate appears to be somewhat conservative.¹⁶ Estimates of lifetimes of assets allowable for tax purposes were obtained separately for assets acquired before 1954 and during and after 1954 from a special Treasury study [23]. The change between the two periods was divided equally between 1954-55 and 1955-56. For 1962 and 1963 the proportional change for the new guidelines relative to existing practice as estimated by the Treasury [24] was applied to the 1961 lifetimes for equipment. Lifetimes assumed were as follows:

| Period | Equipment | Structures |
|---------|-----------|------------|
| 1929-54 | 17.5 | 27.8 |
| 1955 | 16.3 | 25.3 |
| 1956-61 | 15.1 | 22.8 |
| 1962-63 | 13.1 | 22.8 |

Investment functions for equipment and structures for both manufacturing and non-farm, non-manufacturing sectors of the U.S. economy for the years 1931-41 and 1950-63¹⁷ are presented in Table 2. The coeffi-

TABLE 2—INVESTMENT FUNCTIONS FOR MANUFACTURING AND NON-FARM, NON-MANUFACTURING EQUIPMENT AND STRUCTURES FOR 1931-41, 1950-63

| | $\Delta(pQ/c)_t$ | $\Delta(pQ/c)_{t-1}$ | N_{t-1} | $\hat{\alpha}$ | Mean Lag | R_N^2 | R_I^2 | d |

| Manufacturing equipment | .01419 (.00372) | .01242 (.00442) | .6152 (.1001) | .0691 (.0156) | 2.065 (.258) | .7219 | .9566 | 2.036 |
| Manufacturing structures | .00396 (.00131) | .00526 (.00145) | .7658 (.0790) | .0394 (.0126) | 3.840 (.343) | .8475 | .9208 | 2.474 |
| Non-farm, non-manufacturing equipment | .02452 (.00844) | .01460 (.01038) | .4692 (.1342) | .0737 (.0141) | 1.257 (.261) | .6899 | .9616 | 1.738 |
| Non-farm, non-manufacturing structures | .01296 (.00197) | .00227 (.00223) | .8801 (.0322) | .1269 (.0250) | 7.488 (.239) | .9830 | .9908 | 1.435 |

cients associated with $\Delta(p_t Q_t)/c_t$ and $\Delta(p_{t-1} Q_{t-1})/c_{t-1}$, respectively, are estimates of the $\alpha\gamma_0$ and $\alpha\gamma_1$. The coefficient associated with lagged net investment, N_{t-1} , is an estimate of $-\omega$. Using the fact that the coefficients of the distributed lag function sum to unity, an estimate of the elasticity of output with respect to capital may be obtained. This estimate, d , is also presented in Table 2.

Second, the average lag between changes in desired capital and actual investment expenditure as derived from the coefficients of the distributed lag function is presented in Table 2. Finally, Table 2 contains measures of the goodness of fit of the regression— R_N^2 , R_I^2 , and d , the Durbin-Watson ratio. Goodness of fit is measured in two ways: the ratio

¹⁶ A figure suggested by the results of Jorgenson and Griliches [9] is 20 per cent before taxes. This figure excludes capital gains whether realized or unrealized.

¹⁷ The years 1942-1947 are eliminated from the regressions because of the widespread use of nonprice allocation of capital goods during these years.

FIGURE 1

of the explained sum of squares to the total sum of squares for gross investment, R_T^2 ; the ratio of the explained sum of squares to the total sum of squares in net investment, R_N^2 . Of course, gross investment is the variable of interest for policy considerations.

Estimates of the coefficients of the distributed lag function $\{\mu_s\}$ may be calculated from estimates of the parameters γ_0 , γ_1 , and ω by the usual recursion formula.¹⁸ The first fifteen terms of the sequence $\{\mu_s\}$ derived by this technique are presented in Figure 1. The general shape of the distributed lag functions coincides with previous results based on quarterly data. A substantial part of the investment takes place during the year in which the change in desired capital occurs. However, even more occurs in the following year. By assumption the proportions of investment that result from a given change in desired capital decline geometrically in subsequent years. The average lag for investment in equipment is approximately 2 years for manufacturing and about 1.3 years for non-manufacturing. The average lag for structures is considerably longer, ranging from 3.8 years in manufacturing to 7.5 years in non-manufacturing.

¹⁸ This formula is given in D. W. Jorgenson [13].

FIGURE 2a. MANUFACTURING EQUIPMENT

FIGURE 2b. MANUFACTURING STRUCTURES

To give a better notion of the degree of conformity between fitted values of investment and the actual observations, fitted gross investment is plotted against actual gross investment in Figures 2a-2d. Net investment is calculated from the fitted regression; replacement invest-

FIGURE 2c. NON-FARM, NON-MANUFACTURING EQUIPMENT

FIGURE 2d. NON-FARM, NON-MANUFACTURING STRUCTURES

ment, taken as a given datum, is then added to obtain the fitted value of gross investment. Data on replacement investment are also plotted in Figures 2a-2d. Despite the wide variability in levels of gross investment during the period 1931 and 1963, the fitted investment functions pro-

vide an accurate representation of actual investment behavior. In almost every series the largest observation is at least ten times the smallest, so that the goodness of fit of the investment functions provides much stronger confirmation for the underlying theory of investment behavior than functions fitted to postwar data alone.

III. *The Effects of Tax Policy on Investment Behavior*

The effects of a change in tax policy are: (1) an initial burst of net investment which brings the capital stock up to the new desired capital stock, (2) a permanent increase in gross investment resulting from replacement of a larger capital stock, and (3) a proportionate increase in net and gross investment caused by changes in other determinants of desired capital stock. To calculate the magnitudes of these effects for various alternative policies, we have assumed that tax policy has no effect on the before-tax rate of return or on the price of capital goods.

We present results for three actual changes and for one hypothetical change in tax policy: (1) the adoption of accelerated methods for computing depreciation for tax purposes in 1954, (2) the shortening of lifetimes for tax purposes allowed for equipment by the depreciation guidelines of 1962, (3) the investment tax credit of 1962, and (4) the hypothetical adoption of first-year writeoff in 1954. For each of the actual changes in tax policy our procedure is to calculate the rental price of capital on the assumption that the change in policy did not take place. We then calculate the changes in desired capital and investment for the resulting rental price of capital. Desired capital and investment depend on the parameters of the investment function; in our calculations, these parameters are replaced by the estimates given in Table 2 above. For the hypothetical first-year writeoff of investment expenditures beginning in 1954 our procedure is to calculate the rental price of capital under this policy. We then calculate the resulting changes in desired capital and investment from the fitted investment functions, as before.

The reductions in the rental on capital goods brought about in 1954 as a result of accelerated depreciation were as follows:

| | Before Change | After Change |
|--|------------------|-----------------|
| Manufacturing Equipment | .310 | .284 |
| Manufacturing Structures | .207 | .188 |
| Non-Farm, Non-Manufacturing Equipment | .375 | .344 |
| Non-Farm, Non-Manufacturing Structures | .218 | .198 |

Our estimates of the increase in net investment, gross investment, and capital stock resulting from this change are given in Table 3. For comparison the actual levels of net investment, gross investment, and capital stock are given in Table 4.

The effects of the switch to accelerated methods for computing depreciation are quite dramatic. For each of the four classes of assets, the change in depreciation rules results in a substantial increase in desired capital stock. The effects of this increase depend on the time lag between changes in desired capital stock and the resulting net investment.

Although essentially the same pattern prevails for all four classes of assets, it is useful to trace out the effects of tax policy on net investment, gross investment, and capital stock for each class. The peak effect on net investment for manufacturing equipment is attained in 1955 with a level of \$.680 billion (in constant 1954 dollars) or 70.8 per cent of net investment in that year. By 1961, the increase in net investment has fallen to \$.089 billion. Over the whole period 16.9 per cent of the net investment in manufacturing equipment may be attributed to the change in depreciation rules. Similarly, the peak effect for non-farm, non-manufacturing equipment is \$1.214 billion in 1955, or 39.7 per cent of the net investment that took place in that year. Over the 1954-63 period 19.1 per cent of the net investment in non-farm, non-manufacturing equipment may be attributed to the change in depreciation rules. By 1961, the increase in net investment has fallen to \$.193 billion.

The pattern of net investment for structures is similar to that for equipment. For manufacturing structures the peak effect on net investment occurs in 1955 with \$.434 billion or 28.9 per cent of the net investment that took place in that year. The decline of net investment in structures is more gradual. By the end of the 1954-63 period the increase in net investment in manufacturing structures due to the change in depreciation rules in 1954 is still \$.125 billion. Over the whole period 20.8 per cent of net investment may be attributed to the change in depreciation policy. For non-farm, non-manufacturing structures the peak effect on net investment is in 1955 with \$1.246 billion or 17.5 per cent of the net investment that took place. This level falls off to \$.765 billion by 1963, the end of the ten-year period, 1954-63. Over the whole period 15.7 per cent of the net investment in non-farm, non-manufacturing structures may be attributed to the change in depreciation rules.

Since capital stock is simply a cumulation of net investment, the pattern of its behavior may be deduced from that for net investment. For both manufacturing and non-farm, non-manufacturing equipment capital stock rises rapidly over the levels that would have prevailed during the first few years following the adoption of accelerated depreciation methods. More than half of the increase over the period, 1954-63, had already occurred for manufacturing by 1957 and for non-farm, non-manufacturing by 1956. The rise in capital stock for structures is more gradual. Half of the total increase had occurred for manufacturing by 1958 and for non-farm, non-manufacturing by 1959.

Turning to the effects of accelerated depreciation on gross investment, we recall that gross investment is simply the sum of net investment and replacement and that replacement rises in proportion to capital stock. Replacement becomes the dominant component of gross investment in equipment by 1958 for manufacturing and by 1957 for non-farm, non-manufacturing. In both sectors gross investment rises to a peak in 1955 with net investment predominating. As net investment declines, replacement investment rises so that gross investment remains nearly stationary at levels somewhat below the 1955 peak. In manufacturing the increase in gross investment due to accelerated depreciation is \$.549 billion in 1963, which may be compared with the peak level of \$.742 billion in 1955. Similarly, in the non-farm, non-manufacturing sector the increase in gross investment due to accelerated depreciation is \$1.141 billion in 1963, compared with a peak of \$1.417 billion in 1955. The pattern in manufacturing structures is similar to that for equipment. The peak level of investment of \$.446 billion is attained in 1955; the 1963 level is \$.255 billion. For non-farm, non-manufacturing structures net investment continues at a high level throughout the period so that gross investment is roughly constant from 1959 to 1963, when the level is \$1.381 billion. This level may be compared with the relative peak of \$1.319 billion in 1955.

The effect of accelerated depreciation on gross investment during the 1954-63 period may be seen by calculating investment resulting from accelerated depreciation as a proportion of the total investment that took place. For equipment 7.1 per cent of gross investment in manufacturing and 6.8 per cent of the gross investment in non-farm, non-manufacturing may be attributed to accelerated depreciation over the period, 1954-63. For structures the percentages are 11.4 for manufacturing and 9.8 for non-farm, non-manufacturing. Another perspective on the effect of the depreciation rules may be obtained by calculating the proportion of gross investment resulting from the change to total investment at the end of the period. For manufacturing equipment 6.5 per cent of gross investment in 1963 is a result of accelerated depreciation; the corresponding percentage for non-farm, non-manufacturing equipment is 6.3 per cent. The effects of the change are more significant in structures. In 1963, 9.0 per cent of gross investment in manufacturing structures could be attributed to accelerated depreciation; similarly, in non-farm, non-manufacturing structures 9.3 per cent of gross investment could be attributed to the change in depreciation rules.

In 1962 new guidelines for the determination of lifetimes allowable for tax purposes were issued [23]. These guidelines involved a substantial reduction in equipment lifetimes allowable for tax purposes. The

reductions in the rental on capital goods which the change in guidelines brought about in 1962 were as follows:

| | Before Change | After Change |
|---------------------------------------|------------------|-----------------|
| Manufacturing Equipment | .273 | .267 |
| Non-Farm, Non-Manufacturing Equipment | .331 | .323 |

We have calculated the effects on net investment, gross investment, and capital stock resulting from the depreciation guidelines of 1962. These calculations give the increase in equipment investment over the levels that would have prevailed had lifetimes remained at their 1961 levels. The results are given in Table 5.

TABLE 5—CHANGE IN NET INVESTMENT, GROSS INVESTMENT, AND CAPITAL STOCK RESULTING FROM 1962 DEPRECIATION GUIDELINES AND THE INVESTMENT TAX CREDIT, 1962–63 (billions of 1954 dollars)

| Year | 1962 Depreciation Guidelines | | | | | | Investment Tax Credit | | | | | |
|------|------------------------------|------|------|--------------------------------------|------|------|-------------------------|------|------|--------------------------------------|-------|-------|
| | Manufacturing Equipment | | | Non-Farm Non-Manufacturing Equipment | | | Manufacturing Equipment | | | Non-Farm Non-Manufacturing Equipment | | |
| | N | I | K | N | I | K | N | I | K | N | I | K |
| 1962 | .185 | .185 | 0 | .504 | .504 | 0 | .509 | .509 | 0 | 1.388 | 1.388 | 0 |
| 1963 | .287 | .315 | .185 | .559 | .656 | .504 | .792 | .867 | .509 | 1.541 | 1.808 | 1.388 |

The impact of the revised guidelines is substantial, though not as dramatic as the shift to accelerated methods of depreciation in the Internal Revenue Code of 1954. The impact is limited to equipment, whereas the effects of accelerated depreciation were much greater for structures than for equipment. The peak response to the new guidelines, occurring in 1963, is less than half the peak response of investment in equipment to the switch to accelerated depreciation. In percentage terms 14.8 per cent of the net investment in manufacturing equipment in 1963 is due to the change in guidelines; 17.6 per cent of the net investment in non-farm, non-manufacturing equipment is due to the change. The impact on gross investment is proportionately smaller. In 1963 only 3.7 per cent of gross investment in manufacturing equipment is due to the new guidelines; 3.6 per cent of investment in non-farm, non-manufacturing equipment could be attributed to the revised lifetimes.

A second change in tax policy during 1962 was the adoption of a seven per cent investment tax credit for machinery and equipment in the Revenue Act of 1962.¹⁹ Seven per cent of the value of purchases of new

¹⁹ Actually, limitations making the tax credit inapplicable to very short-lived assets reduce its effective rate to about 6.6 per cent. In 1964 its effective rate was raised to around ten per cent by allowing depreciation to be taken on the cost before rather than after the tax credit.

plant and equipment is a credit against tax liability. The depreciation base is reduced by the amount of the tax credit. The remaining 93 per cent is then amortized over the lifetime of the equipment. The reductions in the rental on capital goods which the investment tax credit brought about in 1962 were as follows:

| | Before Change | After Change |
|---------------------------------------|------------------|-----------------|
| Manufacturing equipment | .286 | .267 |
| Non-farm, non-manufacturing equipment | .346 | .323 |

To isolate the effects of the investment tax credit, we have calculated the resulting net investment, gross investment, and capital stock. These calculations give the increase in investment over levels that would have prevailed in the absence of the investment tax credit. This increase is given in Table 5.

The effects of a 7 per cent investment tax credit are quite startling. Although the impact is limited to equipment, the peak response of net investment to the tax credit, occurring in 1963, is greater for both manufacturing and non-farm, non-manufacturing than the response to accelerated methods of depreciation. Fully 40.9 per cent of the net investment in manufacturing equipment in 1963 can be attributed to the investment tax credit. The corresponding percentage for non-farm, non-manufacturing equipment is 48.6 per cent. Of course, the impact of the investment tax credit on gross investment is less startling, but this impact is also quite dramatic. Of the total of \$8.461 billion of investment in manufacturing equipment in 1963, 10.2 per cent can be traced to the effects of the investment tax credit. Similarly, of \$17.982 billion of investment in non-farm, non-manufacturing equipment in the same year, 10.1 per cent can be attributed to the investment tax credit. There can be little doubt that an investment tax credit is a potent stimulus to investment expenditure.

The progressive liberalization of depreciation for tax purposes since 1954 has had an important impact on investment behavior. The investment booms of 1955-57 and beginning in 1962 reflect, in part, the response of investment behavior to the changes in tax policy that took place in 1954 and 1962. According to our calculations, the adoption of accelerated depreciation in the Internal Revenue Code of 1954 resulted in a shift in the composition of investment from equipment to structures. Similarly, the adoption in 1962 of new guidelines and the investment tax credit resulted in a shift of investment from structures to equipment. This shift was especially dramatic for the response to the investment tax credit.

The magnitude of the past response to liberalization of depreciation suggests an investigation of the response to further liberalization. To

take an extreme assumption we can investigate the pattern of investment that would result from complete "expensing" or first-year writeoff of investment. Under such a tax policy expenditures on capital account would be treated in the same way as expenditures on current account. As Vernon Smith [17] has demonstrated, the effects of this policy are the same as the effects of no taxation of business income.²⁰ The reductions in the rental on capital goods which first-year writeoff would have brought about in 1954 are as follows:

| | Before Change | After Change |
|--|------------------|-----------------|
| Manufacturing Equipment | .284 | .214 |
| Manufacturing Structures | .188 | .130 |
| Non-Farm, Non-Manufacturing Equipment | .344 | .260 |
| Non-Farm, Non-Manufacturing Structures | .198 | .137 |

We have calculated the effects on net investment, gross investment, and capital stock resulting from the hypothetical adoption of first-year writeoff in 1954. The changes represent the increment in investment and capital stock over the levels that resulted from accelerated depreciation. The increases in net investment, gross investment, and capital stock are presented in Table 6.

The adoption of first-year writeoff for investment expenditures in 1954 would have resulted in a sharp rise in desired capital for all four classes of assets. The effect of this rise on investment is relatively rapid for equipment; for manufacturing net investment in equipment for 1955 would have been over twice as large as a result of first-year writeoff. The relative increase in equipment investment in the non-farm, non-manufacturing sector would have been somewhat smaller. The increase in net investment in equipment for both sectors would have returned to relatively moderate levels by the beginning of the 1960's. The response is much more gradual for structures than for equipment. The increase in net investment in structures would have remained at substantial levels throughout the 1950's and 1960's. The effects of adoption of first-year writeoff in 1954 on gross investment in both equipment and structures would have been substantial throughout the period 1954-63. By the end of the period the chief effect of this policy would have been an increased level of replacement investment.

IV. Conclusion

We have calculated the effects of changes in tax policy on investment behavior for three major tax revisions in the postwar period: (1) the adoption of accelerated methods for calculating depreciation in the Internal Revenue Code of 1954; (2) the reduction of lifetimes used for calculating depreciation on equipment and machinery in 1962; (3) the

| 1963 | .447 | 1.757 | 8.906 | .538 | 1.114 | 9.214 | .656 | 3.652 | 15.582 | 3.325 | 6.066 | 39.491 |

investment tax credit for equipment and machinery in the Revenue Act of 1962. The effects of accelerated depreciation are very substantial, especially for investment in structures. The effects of the depreciation guidelines of 1962 are significant, but these effects are confined to investment in equipment. The effects of the investment tax credit of 1962 are quite dramatic and leave little room for doubt about the efficacy of tax policy in influencing investment behavior. These three tax policies represent a progressive liberalization of depreciation for tax purposes. To get some idea of the effects of further liberalization we have calculated the impact of the adoption of first-year writeoff of investment expenditures beginning in 1954. This tax policy represents the ultimate liberalization since it is equivalent to treating capital expenditures in the same way as current expenditures for tax purposes. The effects of such a policy on investment expenditure would have been very substantial throughout the period, 1954-63.

MACROECONOMICS OF UNBALANCED GROWTH: THE ANATOMY OF URBAN CRISIS*

By WILLIAM J. BAUMOL

There are some economic forces so powerful that they constantly break through all barriers erected for their suppression. Such, for example, are the forces of supply and demand which have resisted alike medieval efforts to abolish usury and contemporary attempts to control prices. In this paper I discuss what I believe to be another such mechanism which has colored the past and seems likely to stamp its character on the future. It helps us to understand the prospective roles of a wide variety of economic services: municipal government, education, the performing arts, restaurants, and leisure time activity. I will argue that inherent in the technological structure of each of these activities are forces working almost unavoidably for progressive and cumulative increases in the real costs incurred in supplying them. As a consequence, efforts to offset these cost increases, while they may succeed temporarily, in the long run are merely palliatives which can have no significant effect on the underlying trends.

The justification of a macroeconomic model should reside primarily in its ability to provide insights into the workings of observed phenomena. Its aggregation of diverse variables usually deny it the elegance and the rigor that are provided by microeconomic analysis at its best. Yet macro models have succeeded in explaining the structure of practical problems and in offering guidance for policy to a degree that has so far eluded the more painstaking modes of economic analysis. This article hopes to follow in the tradition—the structure of its basic model is rudimentary. Yet it can perhaps shed some light on a variety of economic problems of our generation.

1. *Premises*

Our model will proceed on several assumptions, only one of which is really essential. This basic premise asserts that economic activities can, not entirely arbitrarily, be grouped into two types: technologically progressive activities in which innovations, capital accumulation, and economies of large scale all make for a cumulative rise in output per

* The author is professor of economics, Princeton University. He wishes to thank the Ford Foundation and the National Science Foundation whose grants greatly facilitated completion of this paper. The basic hypothesis was originally developed jointly with William G. Bowen in the study of the performing arts conducted for the Twentieth Century Fund. In this paper there is no attempt to document the illustrative empirical observations though in every case the data have been examined and appear to support the assertions

man hour and activities which, by their very nature, permit only sporadic increases in productivity.

Of course, one would expect that productivity would not grow at a uniform rate throughout the economy so it is hardly surprising that, given any arbitrarily chosen dividing line, one can fit all goods and services into one or the other of two such categories in whatever way the dividing line is drawn. I am, however, making a much stronger assertion: that the place of any particular activity in this classification is not primarily a fortuitous matter determined by the particulars of its history, but rather that it is a manifestation of the activity's technological structure, which determines quite definitely whether the productivity of its labor inputs will grow slowly or rapidly.

The basic source of differentiation resides in the role played by labor in the activity. In some cases labor is primarily an instrument—an incidental requisite for the attainment of the final product, while in other fields of endeavor, for all practical purposes the labor is itself the end product. Manufacturing encompasses the most obvious examples of the former type of activity. When someone purchases an air conditioner he neither knows nor cares how much labor went into it. He is not concerned one way or the other with an innovation that reduces the manpower requirements for the production of his purchase by 10 per cent if the price and the quality of the product are unaffected. Thus it has been possible, as it were, behind the scenes, to effect successive and cumulative decreases in the labor input coefficient for most manufactured goods, often along with some degree of improvement in the quality of the product.

On the other hand there are a number of services in which the labor is an end in itself, in which quality is judged directly in terms of amount of labor. Teaching is a clear-cut example, where class size (number of teaching hours expended per student) is often taken as a critical index of quality. Here, despite the invention of teaching machines and the use of closed circuit television and a variety of other innovations, there still seem to be fairly firm limits to class size. We are deeply concerned when elementary school classes grow to 50 pupils and are disquieted by the idea of college lectures attended by 2000 underclassmen. Without a complete revolution in our approach to teaching there is no prospect that we can ever go beyond these levels (or even up to them) with any degree of equanimity. An even more extreme example is one I have offered in another context: live performance. A half hour horn quintet calls for the expenditure of $2\frac{1}{2}$ man hours in its performance, and any attempt to increase productivity here is likely to be viewed with concern by critics and audience alike.

The difference between the two types of activity in the flexibility of their productivity levels should not be exaggerated. It is a matter of

degree rather than an absolute dichotomy. The jet airplane has increased the productivity per man hour of a faculty member who is going from New York to California to give a lecture. Certainly the mass media have created what may be considered a new set of products that are close substitutes for live performance and by which productivity was increased spectacularly. In addition, there are, as the reader will recognize, all sorts of intermediate activities which fall between the two more extreme varieties. Yet, the distinction between the relatively constant productivity industries and those in which productivity can and does rise is a very real one, and one which, we shall see, is of considerable practical importance.

In addition to the separability of activities into our two basic categories I shall utilize three other assumptions, two of them primarily for ease of exposition. The reader will recognize, as we proceed, that neither is essential to the argument. The first of the incidental premises consists simply in the assertion that all outlays other than labor costs can be ignored. This assertion is patently unrealistic but it simplifies greatly our mathematical model. A second, far more important, and more realistic assumption is that wages in the two sectors of the economy go up and down together. In the long run there is some degree of mobility in all labor markets and consequently, while wages in one activity can lag behind those in another, unless the former is in process of disappearing altogether we cannot expect the disparity to continue indefinitely. For simplicity I will in the next section take hourly wages to be precisely the same in both sectors, but the model is easily complicated to allow for some diversity in wage levels and their movements.

A final inessential assumption which is, however, not altogether unrealistic, asserts that money wages will rise as rapidly as output per man hour in the sector where productivity is increasing. Since organized labor is not slow to learn of increases in its productivity it is likely to adjust its wage demands accordingly. This assumption affects only the magnitude of the absolute price level in our model, and does not influence the relative costs and prices that are the critical elements in the analysis.

2. *A Model of Unbalanced Expansion*

Assume that the economy is divided into two sectors, sector one, in which the productivity of labor is constant, while in sector two output per man hour grows cumulatively at a constant compounded rate, r . Thus we have for the respective values of outputs Y_{1t} and Y_{2t} in the two sectors at time t :

$$(1) \qquad Y_{1t} = aL_{1t}$$

$$(2) \qquad Y_{2t} = bL_{2t}e^{rt}$$

where L_{1t} and L_{2t} are the quantities of labor employed in the two sectors and a and b are constants.

We suppose wages are equal in the two sectors and are fixed at W_t dollars per unit of labor, where W_t itself grows in accord with the productivity of sector 2, our "progressive" sector, so that

$$(3) \quad W_t = We^{rt}. \quad (W = \text{some constant})$$

We may now derive several properties of such a system. First and most fundamental is *Proposition 1*: The cost per unit of output of sector 1, C_1 , will rise without limit while C_2 , the unit cost of sector 2, will remain constant.
proof:

$$C_1 = W_t L_{1t} / Y_{1t} = We^{rt} L_{1t} / a L_{1t} = We^{rt} / a$$

$$C_2 = W_t L_{2t} / Y_{2t} = We^{rt} L_{2t} / b L_{2t} e^{rt} = W / b.$$

Note that the *relative* costs will behave in this manner whether or not wages increase in accord with (3) for we have

$$C_1 / C_2 = (L_{1t} / Y_{1t}) / (L_{2t} / Y_{2t}) = be^{rt} / a.$$

In practice, we would expect in these circumstances that market demand for the output of sector 1 would decline. Suppose, for example, the elasticity of demand for the two outputs were unity in terms of prices which were proportionate to costs. Then relative outlays on the two commodities would remain constant, i.e., we would have

$$\frac{C_1 Y_1}{C_2 Y_2} = \frac{We^{rt} L_{1t}}{We^{rt} L_{2t}} = \frac{L_{1t}}{L_{2t}} = A(\text{constant}).$$

Hence the output ratio of the two sectors would be given by

$$Y_1 / Y_2 = a L_{1t} / b L_{2t} e^{rt} = aA / be^{rt}$$

which declines toward zero with the passage of time. Thus we have *Proposition 2*: In the model of unbalanced productivity there is a tendency for the outputs of the "nonprogressive" sector whose demands are not highly inelastic to decline and perhaps, ultimately, to vanish.

We may inquire, however, what would happen if despite the change in their relative costs and prices the magnitude of the relative outputs of the two sectors were maintained, perhaps with the aid of government subsidy, or if demand for the product in question were sufficiently price inelastic or income elastic. Then we would have

$$(b/a) Y_1 / Y_2 = L_1 / L_2 e^{rt} = K.$$

Let $L = L_1 + L_2$ be the total labor supply. It follows that

$$(4) \quad L_1 = (L - L_1)Ke^{rt} \quad \text{or} \quad L_1 = LKe^{rt} / (1 + Ke^{rt})$$

and

$$(5) \quad L_2 = L - L_1 = L/(1 + Ke^{rt}).$$

Hence, as t approaches infinity, L_1 will approach L and L_2 will approach zero. Thus we have *Proposition 3*: In the unbalanced productivity model, if the ratio of the outputs of the two sectors is held constant, more and more of the total labor force must be transferred to the non-progressive sector and the amount of labor in the other sector will tend to approach zero.

Finally, we may note what happens to the overall rate of growth of output in the economy if the output ratio for the two sectors is not permitted to change. We may take as an index of output a weighted average of the outputs of the two sectors:

$$I = B_1Y_1 + B_2Y_2 = B_1aL_1 + B_2bL_2e^{rt}$$

so that by (4) and (5)

$$I = L(KB_1a + B_2b)e^{rt}/(1 + Ke^{rt}) = Re^{rt}/(1 + Ke^{rt})$$

where

$$R = L(KB_1a + B_2b).$$

Therefore

$$\begin{aligned} dI/dt &= R[re^{rt}(1 + Ke^{rt}) - Kre^{2rt}]/(1 + Ke^{rt})^2 \\ &= rRe^{rt}/(1 + Ke^{rt})^2. \end{aligned}$$

As a result, the percentage rate of growth of output will be

$$(dI/dt)/I = r/(1 + Ke^{rt})$$

which declines asymptotically toward zero as t increases. We have, then, arrived at *Proposition 4*: An attempt to achieve balanced growth in a world of unbalanced productivity must lead to a declining rate of growth relative to the rate of growth of the labor force. In particular, if productivity in one sector and the total labor force remain constant the growth rate of the economy will asymptotically approach zero.

3. Discussion of the Propositions

The logic of the entire analysis can be restated rather simply in intuitive terms. If productivity per man hour rises cumulatively in one sector relative to its rate of growth elsewhere in the economy, while wages rise commensurately in all areas, then relative costs in the nonprogressive sectors must inevitably rise, *and these costs will rise cumulatively and without limit*. For while in the progressive sector productivity increases will serve as an offset to rising wages, this offset must be smaller in the

nonprogressive sectors. For example (ignoring nonwage costs) if wages and productivity in the progressive sector both go up 2 per cent per year, costs there will not rise at all. On the other hand, if in the nonprogressive sector productivity is constant, every rise in wages must yield a corresponding addition to costs—a two per cent cumulative rise in wages means that, year in year out, costs must be two per cent above those of the preceding year. Thus, the very progress of the technologically progressive sectors inevitably adds to the costs of the technologically unchanging sectors of the economy, unless somehow the labor markets in these areas can be sealed off and wages held absolutely constant, a most unlikely possibility.

We see then that costs in many sectors of the economy will rise relentlessly, and will do so for reasons that are for all practical purposes beyond the control of those involved. The consequence is that the outputs of these sectors may in some cases tend to be driven from the market. If their relative outputs are maintained, an ever increasing proportion of the labor force must be channeled into these activities and the rate of growth of the economy must be slowed correspondingly.

4. *Some Applications*¹

These observations can be used at once to explain a number of observed phenomena. For example, there is evidence that an ever increasing portion of the nation's labor force has been going into retailing and that a rising portion of the cost of commodities is accounted for by outlays on marketing. Now there have been several pronounced changes in the technology of marketing in recent decades: self service, the supermarket, and prewrapping have all increased the productivity per man hour of the retailing personnel. But ultimately, the activity involved is in the nature of a service and it does not allow for constant and cumulative increases in productivity through capital accumulation, innovation, or economies of large-scale operation. Hence it is neither mismanagement nor lack of ingenuity that accounts for the relatively constant productivity of this sector. Since some sort of marketing effort is an inescapable element in economic activity, demand for this service is quite income elastic. Our model tells us what to expect in this case—cumulatively increasing costs relative to those of other economic activities, and the absorption of an ever growing proportion of society's resources by this sector—precisely what seems to have been observed.

Higher education is another activity the demand for whose product seems to be relatively income elastic and price inelastic. Higher tuition charges undoubtedly impose serious hardships on lower-income stu-

¹ Some of the ideas in this section arose out of discussions with Eugene Beem of Sperry and Hutchinson.

dents. But, because a college degree seems increasingly to be a necessary condition for employment in a variety of attractive occupations, most families have apparently been prepared to pay the ever larger fees instituted in recent years. As a result higher education has been absorbing a constantly increasing proportion of per capita income. And the relatively constant productivity of college teaching leads our model to predict that rising educational costs are no temporary phenomenon—that they are not a resultant of wartime inflation which will vanish once faculty salaries are restored to their prewar levels. Rather, it suggests that, as productivity in the remainder of the economy continues to increase, costs of running the educational organizations will mount correspondingly, so that whatever the magnitude of the funds they need today, we can be reasonably certain that they will require more tomorrow, and even more on the day after that.

But not all services in the relatively constant productivity sector of the economy face inelastic demands. Many of them are more readily dispensable than retailing and education as far as individual consumers are concerned. As their costs increase, their utilization tends therefore to decrease and they retreat into the category of luxury goods with very limited markets or disappear almost completely. Fine pottery and glassware produced by the careful labor of skilled craftsmen sell at astronomical prices, though I am told the firms that produce them earn relatively little profit from these product lines which they turn out primarily for prestige and publicity, obtaining the bulk of their earnings from their mass production activities. Fine restaurants and theaters are forced to keep raising their prices, and at least in the case of the latter we know that volume is dwindling while it becomes ever more difficult for suppliers (the producers) to make ends meet.

An extreme example of an activity that has virtually disappeared is the construction (and, indeed, the utilization) of the large and stately houses whose operation even more than their construction allows for little in the way of enhanced productivity, and whose rising costs of operation have apparently decreased their salability even to the wealthy.

These observations suggest something about the likely shape of our economy in the future. Our model tells us that manufactures are likely to continue to decline in relative cost and, unless the income elasticity of demand for manufactured goods is very large, they may absorb an ever smaller proportion of the labor force, which, if it transpires, may make it more difficult for our economy to maintain its overall rate of output growth.

The analysis also suggests that real cost in the “nonprogressive” sectors of the economy may be expected to go on increasing. Some of the

services involved—those whose demands are inelastic—may continue viable on the free market. Some, like the theater, may be forced to leave this market and may have to depend on voluntary public support for their survival. Our hospitals, our institutions of private education and a variety of other nonprofit organizations have already long survived on this basis, and can continue to do so if the magnitude of contributions keeps up with costs. Some activities will either disappear or retreat to a small scale of operation catering primarily to a luxury trade. This fate may be in store for restaurants offering true *haute cuisine* and it is already the case for fine hand-worked furniture and for clothes made to measure. Some activities, perhaps many of the preceding among them, will fall increasingly into the hands of the amateurs who already play a considerable role in theatrical and orchestral performances, in gastronomy, in crafts such as woodworking and pottery. Finally, there is a considerable segment of nonprogressive activity that is dependent on tax support. Some of the problems that go with this position will be considered in the remainder of this paper.

In all the observations of this section there is one implicit underlying danger that should not escape the reader: the inherent threat to quality. Amateur activity has its virtues, as an educational device, as a good use for leisure time and so forth. But in a variety of fields it offers a highly imperfect substitute for the highly polished product that can be supplied by the professional. Unbalanced productivity growth, then, threatens to destroy many of the activities that do so much to enrich our existence, and to give others over into the hands of the amateurs. These are dangers which many of us may feel should not be ignored or taken lightly.

5. *On the Financial Problem of the Cities*

One of the major economic problems of our times is the crisis of the larger cities. Together with their suburban periphery the cities are attracting ever greater segments of our population. Yet at least the core of the metropolis is plagued by a variety of ills including spreading blight as entire neighborhoods deteriorate, increasing pollution of its atmosphere, worsening traffic, critical educational problems, and, above all, mounting fiscal pressures. The financial troubles are perhaps central to the entire issue because without adequate funds one cannot hope to mount an effective attack on the other difficulties. More than one reform mayor has taken office determined to undertake a radical program to deal with the city's difficulties and found himself baffled and stymied by the monstrous deficit which he discovered to be hanging over him, a deficit whose source appeared to have no reasonable explanation. There seems in these cases to be no way to account for the growth in the city's financial needs—for the fact that a municipal budget far above that

which was roughly adequate a decade earlier threatens to disrupt seriously the city's most vital services today. Where the political process is involved it is easy to blame growing costs on inefficiency and corruption but when they take office, reform administrations seem consistently puzzled by their inability to wring out the funds they require through the elimination of these abuses.

A critical element in the explanation becomes clear when we recognize how large a proportion of the services provided by the city are activities falling in the relatively nonprogressive sector of the economy. The bulk of our municipal expenditures is devoted to education which, as we have already seen, offers very limited scope for cumulative increases in productivity. The same is true of police, of hospitals, of social services, and of a variety of inspection services. Despite the use of the computer in medicine and in traffic planning, despite the use of closed circuit television and a variety of other devices, there is no substitute for the personal attention of a physician or the presence of a police patrol in a crime-ridden neighborhood. The bulk of municipal services is, in fact, of this general stamp and our model tells us clearly what can be expected as a result. Since there is no reason to anticipate a cessation of capital accumulation or innovation in the progressive sectors of the economy, the upward trend in the real costs of municipal services cannot be expected to halt; inexorably and cumulatively, whether or not there is inflation, administrative mismanagement or malfeasance, municipal budgets will almost certainly continue to mount in the future, just as they have been doing in the past. This is a trend for which no man and no group should be blamed, for there is nothing that can be done to stop it.

6. *The Role of Static Externalities*

Though these may be troubles enough for the municipal administrator, there are other compelling forces that plague him simultaneously. Among them are the general class of externality problems which have so long been the welfare economist's stock in trade.

Since the appearance of Marshall's and Pigou's basic writing in the area a most significant development has been the growing impact of external costs on urban living. No longer are road crowding and smoke nuisance only quaint cases serving primarily as textbook illustrations. Rather, they have become pressing issues of public concern—matters discussed heatedly in the daily press and accorded serious attention by practical politicians. Newspapers devote headlines to an engineer's prediction that the human race is more likely to succumb to its own pollutants than through a nuclear holocaust, and report with glee the quip that Los Angeles is the city in which one is wakened by the sound of birds coughing.

Now there are undoubtedly many reasons for the explosion in external

costs but there is a pertinent observation about the relationship between population size in a given area and the cost of externalities that seems not to be obvious. It is easy to assume that these costs will rise roughly in proportion with population but I shall argue now that a much more natural premise is that they will rise more rapidly—perhaps roughly as the square of the number of inhabitants. For example, consider the amount of dirt that falls into the house of a typical urban resident as a result of air pollution, and suppose that this is equal to kn where n is the number of residents in the area. Since the number of homes in the area, an , is also roughly proportionate to population size, total domestic soot-fall will be equal to soot per home times number of homes $= kn \cdot an = akn^2$. Similarly, if delays on a crowded road are roughly proportionate to n , the number of vehicles traversing it, the total number of man hours lost thereby will increase roughly as n^2 , since the number of passengers also grows roughly as the number of cars. The logic of the argument is simple and perhaps rather general: if each inhabitant in an area imposes external costs on every other, and if the magnitude of the costs borne by each individual is roughly proportionate to population size (density) then since these costs are borne by each of the n persons involved, the total external costs will vary not in proportion with n but with n^2 . Of course I do not maintain that such a relationship is universal or even that it is ever satisfied more than approximately. Rather I am suggesting that, typically, increases in population size may plausibly be expected to produce disproportionate increases in external costs—thus pressures on the municipality to do something about these costs may then grow correspondingly.

7. Cumulative Decay and Dynamic Pareto Optimality

Economic theory indicates yet another source of mounting urban problems. These are the processes of cumulative urban decay which once set in motion induce matters to go from bad to worse. Since I have discussed these elsewhere I can illustrate the central proposition rather briefly. Public transportation is an important example. In many urban areas with declining utilization, frequency of service has been sharply reduced and fares have been increased. But these price rises have only served to produce a further decline in traffic, leading in turn to yet another deterioration in schedules and another fare increase and so on, apparently *ad infinitum*. More important, perhaps, is the logic of the continued flight to the suburbs in which many persons who apparently would otherwise wish to remain in the city are driven out by growing urban deterioration—rising crime rates, a growing number of blighted neighborhoods, etc. Once again, the individuals' remedy intensifies the community's problems and each feeds upon the other. Those who leave

the city are usually the very persons who care and can afford to care—the ones who maintain their houses, who do not commit crimes, and who are most capable of providing the taxes needed to arrest the process of urban decay. Their exodus therefore leads to further deterioration in urban conditions and so induces yet another wave of emigration, and so on.²

It is clear that these cumulative processes can greatly increase the financial pressures besetting a municipality and can do so in a variety of ways: they can increase directly municipal costs by adding to the real quantities of inputs required for the upkeep of buildings, to maintain levels of urban sanitation, to preserve the level of education attained by an average resident, etc.; they can reduce the tax base—the exodus of more affluent urban inhabitants cause a decline in the financial resources available to the city; and with the passage of time the magnitude of the resources necessary to arrest and reverse the cumulative processes itself is likely to grow so that the city may find it increasingly difficult to go beyond programs that slow the processes slightly.³

² As is to be expected, such dynamic processes may be monotonic or oscillatory, stable or unstable. As examples we might expect the public transportation scheduling problem to grow monotonically while automotive road crowding may be inherently oscillatory. More specifically, let f represent frequency of public bus departure and p be the number of bus passengers. We would expect the relevant relationships to be something such as

$$\begin{aligned} p_t &= a + bf_t && \text{(demand for public transport) and} \\ f_{t+1} &= w + vp_t && \text{(lagged public transport supply response)} \end{aligned}$$

so that

$$f_{t+1} = w + av + vbf_t$$

in which the coefficient vb is presumably positive. On the other hand, if D represents average delay on some road and A is the volume of automotive traffic, the corresponding relationships would be

$$\begin{aligned} D_t &= a' + b'A_t && \text{(delay grows with traffic volume) and} \\ A_{t+1} &= w' - v'D_t && \text{(delays today lead to lower traffic tomorrow)} \end{aligned}$$

so that we have a negative coefficient $-b'v'$ in the difference equation

$$A_{t+1} = w' - a'v' - b'v'A_t$$

Since monotonic and oscillatory time paths correspond respectively to positive and negative variable coefficients in a first-order difference equation, our result follows. An intuitive explanation is fairly simple in each case: increased automotive traffic today causes delays and so may reduce traffic tomorrow. But a decline in number of passengers which causes a deterioration in service leads to still another fall in volume.

As stated, the time path in each case may be stable. But in the latter case, even though the declines will not be unbounded, the limit toward which they tend may be very low and totally unacceptable as a matter of public policy.

³ I have argued that the cumulative processes involve what may be considered dynamic externalities. Each passenger who uses public transportation less frequently imposes the increased likelihood of poorer schedules not only on himself but on others as well. As a result these processes will yield results that do not maximize social welfare. For the private and social marginal rates of transformation between present and future will then differ from one another. The individual will tend to cut down on his use of public transportation by an amount greater

8. *Conclusion—The Financial Problems of the Large City*

The story is perhaps completed if we add to the preceding observations the fact that each city is in competition with others and with its own surrounding areas for industry and for people with the wherewithal to pay taxes. No city government acting alone can afford to raise its tax rates indefinitely. Even if they were politically feasible, mounting tax rates must eventually produce diminishing and perhaps even negative returns as they depress the tax base further.

We can now quickly pull the pieces of our story together. We have just seen that our municipalities are perhaps unavoidably subject to a variety of growing financial pressures: the limited sources of tax funds, the pressures imposed by several processes of cumulative decay, the costs of externalities which seem to have a built-in tendency to rise more rapidly than the population. These phenomena imply that the activities of the municipality will have to be expanded if standards of city life are to be maintained. But the funds available for the purpose are extremely limited. And over all this hangs the shadow cast by our model of unbalanced growth which has shown that the costs of even a constant level of activity on the part of a municipal government can be expected to grow constantly higher.

The picture that has been painted is bleak. It suggests strongly that self-help offers no way out for our cities. All of this would then appear to offer stronger theoretical support for the Heller-Pechman proposal that the federal government can provide the resources necessary to prevent the serious crisis that threatens our larger urban communities and whose effects on the quality of life in our society may become one of the nation's most serious economic problems.

than that which is optimal because he himself does not bear all of the costs of his action. There is a marginal rate of transformation between the utility derived from public transportation today and that obtainable from transportation tomorrow. If relative prices do not equal that marginal rate of transformation a misallocation of resources is likely to result. The consequences may even be what might be called Pareto-nonoptimal. That is, everyone may be harmed. For example, when automobile traffic becomes sufficiently bad it may become clear that everyone will be better off if passenger cars are banned completely from the downtown area in order to make possible a faster, more efficient public transportation system.

THE ECONOMICS OF TECHNOLOGICAL CHANGE AND THE DEMISE OF THE SHARECROPPER

By RICHARD H. DAY*

Ten years ago, at the University of Oxford, a lecturer on political economy laid it down as axiomatic that science and invention, the division of labor, the law of diminishing returns, could do little to save human labor on the farm.

ELLIS AND RUMELY: *Power and the Plow* (1911)

The economic history of a region is determined by a complicated interaction among geological, biological, technological, social, and economic forces. A vivid portrayal of this process is found in the recent history of the rural American south; the resulting interplay of economic and social movements has been displayed there with irony and violence. Beginning gradually in the late 1930s, the adoption of labor saving technology increased rapidly through the late 1940s and early 1950s. In some cases, the diffusion of a new technique grew by more than 100 per cent per annum.¹ Greatly lowered physical labor coefficients of new techniques created relatively profitable investment opportunities by substituting capital intensive, low variable cost methods for labor intensive, high variable cost methods of production.

A similar process was also at work in other parts of the United States. From 1940 to 1960 the index of man hours of farm work dropped from 191 to 92 for the United States as a whole and in the Delta States of Alabama, Louisiana, and Mississippi from 247 to 93. On the other hand, output per man hour in the production of cotton

*The writing of this paper was financed by a grant from the National Science Foundation. The research on which it is based was initiated in the Farm Production Economics Division, ERS, U.S. Department of Agriculture. It owes much to the encouragement and expert consultation of Glen T. Barton, Grady B. Crowe, Robert V. Glasgow and E. L. Langsford, all of that organization. The study was enhanced by the support of the National Cotton Council while the author was on leave from the U.S. Department of Agriculture. It is a pleasure to thank George Townsend and Claude Welch for making that arrangement possible. James Hand, Jr., former special assistant to the President, of Rolling Fork, Mississippi, offered advice and insights indispensable in tailoring the model to local realities. Criticisms of my colleagues in the economics department at the University of Wisconsin, Ralph Andreano, Glen Cain, Theodor Heidhues and Jeffrey Williamson, are keenly appreciated. I am also indebted to the referee, Karl Fox, of Iowa State University, whose cogent criticisms have, I hope, led to a very considerable improvement in the text.

¹Examples were the adoption of highly mechanized rice cultivation methods and self-propelled combines. See Day [3, p. 92].

alone increased more than threefold from an index of 36 to one of 127 [11, p. 46] [4] [9].

The human counterpart of these technical facts was an exodus of 17 million people from U.S. farms. In Mississippi, where the concentration of population in agriculture was much higher than for the nation as a whole, almost a million people left agriculture—a decline of 62 per cent in two decades. In the ten counties of the Mississippi Delta the decline in the rural farm population was also 62 per cent—a drop of 54 per cent occurring from 1950 to 1960 alone.²

During these years agricultural economists focussed on problems of agricultural surplus and policies of control. At a time when the rest of the economy sluggishly ignored the growing influx of displaced agricultural workers, economists and popular commentators ironically suggested policies that would move resources out of agriculture even faster.

In accordance with the policy concerns of that time I attempted to estimate the influence of technology on supplies of agricultural commodities. A “recursive programming model” was developed and applied to a small but more or less representative southern area. But it is evident that this dynamic model of production and technology is equally a dynamic model of resource utilization and labor demand. Moreover, in the shadow of the labor requirements generated by the model moves the history of changing farm organization and emigration. This side of the story received little attention in my initial report.³ Because of its current relevance it seems worth telling now [10] [15].

In the next section the dynamic model of field crop production is briefly described in nontechnical terms. The results of its application to the “Mississippi Delta” are presented in the following two sections. The first of these displays the derived trends in output, technology, and productivity; the second focuses on the demand for labor and the central hypothesis of the paper: the “two-stage push off the farm.” These are followed by a brief section on population effects where collateral census data are given. The interested reader will find a mathematical description of the model in an appendix.

It is important to recognize that the economic model presented here can generate no data beyond those inherent in already known facts. Instead it explains well-known events in terms of basic economic principles. Still it is possible, if the model’s explanatory power is affirmed, to estimate variables for which little quantitative information is avail-

² See Tables 3 and 4.

³ Day [3, Part III, “A Dynamic Production Model, Production Response of Cotton and Alternative Field Crops in the Mississippi Delta, 1940-1957”].

able. Here we do have excellent quantitative data on production. These data are used to test the model. The evidence suggests that the model is correct in essentials if not in every detail. On this inference are based my new estimates of the derived demand for labor and of labor productivity.

Recursive programming provides a general method for studying processes of economic development. It describes how development at once creates new opportunities and generates binding limitations; how it presents a counterpoint of growth and decay. Suitably modified for special properties of time and place, models similar to the one described here should be equally useful for investigating production, investment, and technological change and their consequences in almost any industry.⁴

I. *A Dynamic Model of Production*

A. *The Region and Its Technologies*

My initial study dealt with a small, relatively homogeneous and highly productive part of the south, the alluvial plains of the Mississippi River, or, as it is commonly known, "the Mississippi Delta."⁵ In the 1930s the area was dominated by sharecroppers with mule-powered, small-unit production. Mechanization was introduced in stages, first affecting land preparation and cultivation as tractor power displaced mules, then handweeding as flame throwers and herbicides were applied, and finally harvesting as mechanical cotton pickers replaced the sharecropper and his family. To summarize this picture, four representative technologies were constructed. They were: *Stage I*: Sharecropper unit. Mule-powered cultivation, hand picking of cotton and corn. *Stage II*: Partial mechanization of preharvest operations on the operator's share of the plantation. Tractor-powered land preparations; mule-powered cultivation; handpicking of cotton and corn; small-scale combines for harvesting soybeans, oats; three-man hay balers for hay crops. *Stage III*: Complete mechanization of pre-harvest operations except some handweeding of cotton and corn. Handpicking of cotton.

⁴Subsequent applications to agriculture are Schaller and Dean [12] and Heidhues [7]. A model of urban land development has been proposed by Schlager [13] and one of the U.S. iron and steel industry is described by Tsao [14]. A model that comes closest to the one described here in those aspects that deal with the regional impact of technology on labor demand is being developed in the Social Systems Research Institute by William Tabb and the author. It deals with the U.S. coal mining industry.

⁵The area to which the quantitative model was applied includes the Mississippi State counties of Bolivar, Coahoma, Humphreys, Issaqueno, Leflore, Quitman, Sharkey, Sunflower, Tallahatchie, Tunica and Washington. This small area is similar to the entire Delta region that includes in addition State Economic Areas 7a, 7b, 8a and 8b of Arkansas, Areas 1, 2 and 3 of Louisiana, and Areas 9a and 9b of Missouri. See *State Economic Areas*, U.S. Department of Commerce, Bureau of the Census, 1954.

Complete mechanization of corn. Self-propelled combines for oats and soybeans; one-man hay balers for hay crops. *Stage IV*: Complete mechanization, introduction of rice, a very small amount of hand-weeding of cotton remaining.

These omit some detail in the variety of technologies actually employed. However, a detailed analysis of costs indicated that the main differences likely to have had any economic importance were included.

B. Inputs and Outputs

Decisions involving the application of each technology to three different soil groupings at up to four levels of fertilization were included. In all, about a hundred alternative production processes were used to describe the region's basic set of agricultural opportunities. The process outputs included the production of cotton lint and cotton seed, corn, soybeans, oats, rice, soybean hay, alfalfa, and lespedeza hay, and the utilization of 36 variable inputs including labor, power, machinery, materials, and custom operations. The labor inputs included unskilled labor for chopping weeds, handpicking labor for cotton, tractor drivers, and special machine operators. The first two were almost always provided by sharecroppers, or by displaced sharecroppers in the form of resident or nonresident day laborers. Special machine operators receive a wage premium above tractor drivers and represent a special skill level because of their requirement to make timely repairs in the field in addition to routine operations.

C. Net Returns, Expectations, and the Profit Objective

Price series for outputs and inputs developed from a variety of sources made it possible to compute "per acre net returns" for each year, 1939-1958. Of course, returns are not known at the time the crop is planted and must be guessed by the farmer when he makes his decisions. Farmers' guesses of future prices are based on a variety of sources. The one most amenable to quantitative analysis is the immediate past. For this reason the previous year's prices were used as a first approximation, and this appears to be good enough for useful results.

Because farmers don't know what prices will be, it is useless to assume that they actually maximize profits. On the other hand, it is not useless to suppose that they try to improve profits given their information about the past and their uncertain guesses about the future. Accordingly, the model includes an objective function that represents the farmer's effort to decide process levels (that is the acreage devoted to each product, technology, soil class, fertilizer combination) that will increase total profits.

D. Constraints on Choice

The choice among production opportunities is constrained by land availability, machine capacities, supplies of off-farm inputs, uncertainty, and by the acreage allotments of federal farm policies. These forces are represented by a set of 35 dynamic inequalities that relate the magnitude of these factors to production decisions the preceding year. A brief description of them will complete the resume of the dynamic production model.

Land availability for the region as a whole is a more or less fixed factor. Some land clearing and draining is still taking place but its effects within the time period considered here are negligible. Land can, of course, be bought and sold on the regional land market, but this real estate activity was not included. Rather, my study focussed on the growth and decline of specific technologies. This was not because changes in farm size are uninteresting or unimportant, but because they are essentially derived from investment in capital intensive production. Three land constraints representing the regional availabilities of the three major soil groupings were included.

In order to avoid the complexities of full-blown capital theories and at the same time to emphasize the role of technological change, a simple scheme of representing investment in machine capacities was adopted. I have called it the "maximal potential growth principle," which is based on the empirical observation that "production can be expanded in a geometric ratio . . . during a given unit time period."⁶ Behind it lies the basic logic of production in time that governs the growth of industries generally, and the principles of learning that influence the adoption of new techniques. The former limits the supply of machinery from the manufacturing sector and the latter limits the demand for machinery at any one time by farmers. These two forces conspire to produce an upper bound on the utilization of a given technique during a given year.

Consequently, investment in the new technique is limited in the model to not more than a given proportional increase over the preceding period's utilized capacity. Whether investment proceeds to this limit is determined in the model by farmers' efforts to improve profits. Investment is pushed to the limit only if it accords with the objective of increasing production in a direction that increases profits as the latter can be judged from past experience. Otherwise, it falls short of the limit by a determinate amount, or is zero. The amount of investment is determined by the model, but its limit is predetermined as a behavioral characteristic of the region. This treatment is not a necessary part of

⁶ M. K. Wood observed this "law" in the aircraft industry [16]. For an exegesis of the concept in terms of agriculture see [3, pp. 89-92] or [1].

the method of analysis employed. Rather it is a practical expedient for building a model in a reasonably short period of time that includes investment and emphasizes technological change.⁷

Variable factors are those inputs that—to the individual firm—appear to be available in unlimited supplies at going prices. But what is true as an appearance for the firm is categorically false as a reality for the industry or the region of which it is a part. Though each firm may ignore its negligible effects on variable input markets, that market must strike a balance between available supplies and existing demands for the groups as a whole. This commonplace principle of standard economic theory is unfortunately difficult to accommodate quantitatively because of the rich structure of marketing activities in the “real world.” Yet it is not difficult to allow for the fact that the total amount of a given variable factor in a region is limited at a given point in time to display its effects on production activities.

In the present study the limited supplies of unskilled labor and of commercially produced nutrients were treated as fixed at the time of the production decision. They were assumed to follow “exogenously” determined trends over the history of the period considered. We thus focussed attention on the *effects* of the emmigration of labor and the explosive increase in the use of commercial nitrogen, leaving an *explanation* of those two diverse movements to more general studies. The “pull” of labor from the farm to the village and from the farm and village to industrial centers in the south and north was not explained by the model either. Yet, as we shall show below, our results indicate something quite significant about that pull all the same.

Attention has already been called to the uncertain guesses about the future that direct farmers’ decisions. This uncertainty restrains in any one year the change in acreage of a given crop. In the model this restraint is represented by behavioral bounds that are determined as proportional increases or decreases over the preceding year’s acreages. They circumscribe the flexibility with which the farmer—and therefore the region—responds to changing economic conditions.⁸

⁷For a much more elaborate approach to investment see Heidhues [7]. His concern is with agricultural adjustment in Germany to EEC policy. His methodology is quite similar.

⁸This approach was first used by J. M. Henderson [6]. For a further elaboration see [3, pp. 86-89] or [1]. I should have preferred to accommodate uncertainty in a much different, theoretically more meaningful way, by representing its effects through a stochastic, “risk programming” model, in that way treating the crop selection problem much like the “portfolio selection” problem to which it is so closely similar. But the difficulty of developing such a model without sacrificing detail in what I thought was the more important technological aspects of the study deterred us from that line of development. This “behavioral” approach has the virtue of operationality given current model solving capabilities. It also appears to come very close to the kind of considerations that are really made by the farmer. It has an empirical justification on that account alone.

During the 1940-1958 period the primary "instrumental variables" controlled by federal farm policy were commodity price supports and acreage allotments. Price supports are easily included in the model by replacing price expectations by the support values, whenever the latter were above the former. Allotments simply introduce an added constraint on the acreage totalled for all technologies, soils, and fertilizer levels for a given crop. Cotton had such restrictions in 1940-1943, 1951, 1954-1957, while rice had allotments in 1955-1957.

E. Review of the Recursive Programming Model and How it Works

The model that emerges from the constituents just described is applied to the Mississippi Delta. The objective criterion and the set of constraints are computed for the region as a whole and form a sequence of recursively dependent linear programming problems. The solution of each problem in the sequence approximates the aggregate choice of a large number of similar firms.⁹

The solution procedure begins with an initial set of capacities and expected net returns. The corresponding linear programming problem generates a solution that estimates the acreage of each process, the expected output of each crop, the utilization of each input and the increase—or decrease—in the capacity of each quasifixed factor. These are then used to estimate the availabilities of capacities and the magnitude of the uncertainty constraints for the succeeding period, which together with the exogenously determined supplies of labor and nitrogen, the fixed supply of land, and the actual prices of the given period yield the programming problem for the succeeding year. This chain of constrained maximizing problems is thus solved step by step for each period under consideration. The procedure was applied to data for the Mississippi Delta for the period 1939-1957, generating estimates of production, investment, land and labor utilization for the years 1940-1958 [3, pp. 193-220].

II. Trends in Output, Technology, and Productivity

The Crop Reporting Board (CRB) and the Agricultural Census data on harvested acres were used to test the model. The comparisons are shown in Figure 1 for the major field crops. They are reasonably good for all except oats. In the latter case, the evaluation is based on a shorter period because of missing CRB data. The census data indicate that, even for this crop, the model estimates are not far removed from the trend, at least for the 1940-1950 decade.¹⁰

⁹ For a discussion of the aggregation problem and the justification for this microeconomic interpretation see Day [2].

¹⁰ The proportion of variation in the CRB data "explained" were for cotton .91, corn .72, soybeans .89, oats -.05, and rice .83. Unlike regression models where the method of

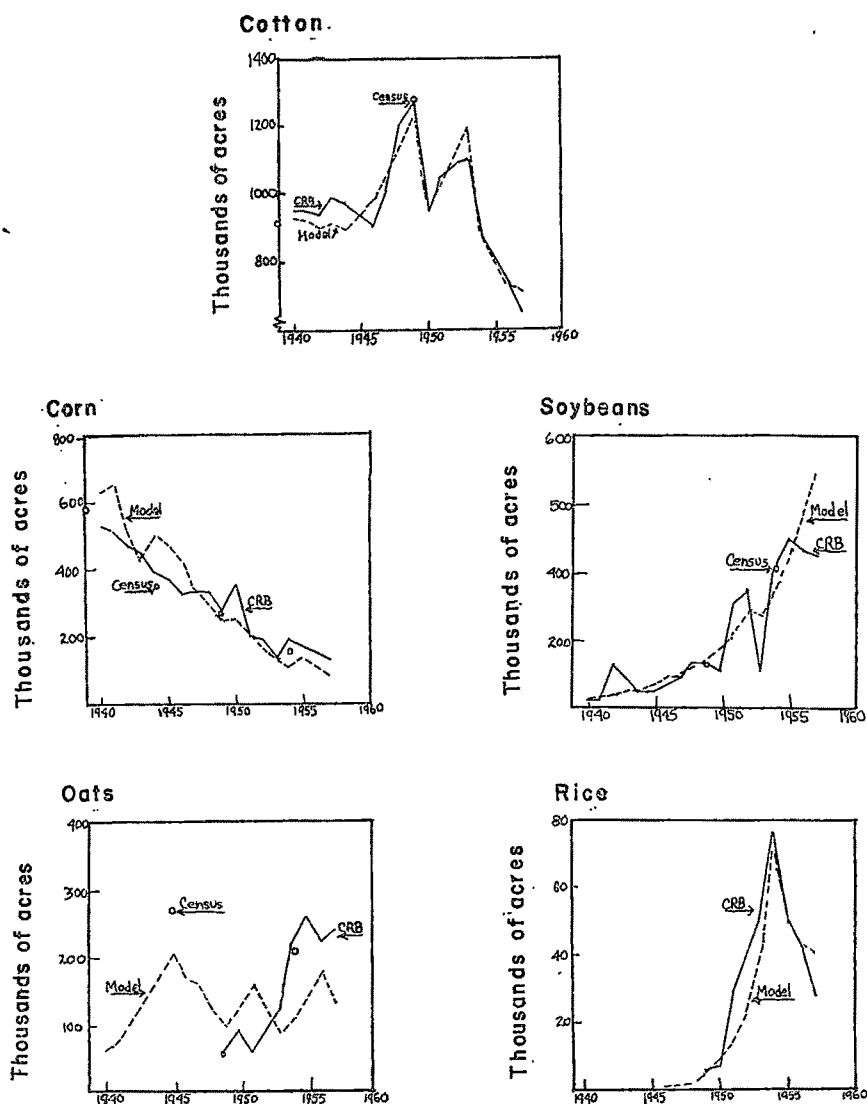

FIGURE I. TRENDS IN OUTPUT: CROP ACREAGES

These graphical comparisons indicate that the model is essentially correct even though it is incapable of estimating acreage changes with exact precision. On this evidence I indeed accept the model's general

estimation guarantees coefficients of determination between zero and one, recursive programming gives coefficients that may be large negative numbers, though, like their regression counterparts they can never exceed one. This explains the negative figure for oats.

validity¹¹ and in this and the next section turn to an exploration of its implications. Some of the latter relate to population movements. For this reason census data can add indirect information about the model's veracity. This is done in a section on population effects.

The top panel of Figure 1 shows the effect on cotton acreages of allotments during the years 1940-1943, 1950, and after 1954. The rapid buildup of cotton acreage during 1944-1949 and again during 1951-1954 contrasts sharply with the allotment years. These trends illustrate the powerful brake of production controls when they are in effect and the growth potential of the crop when unrestricted by government controls. The steady abandonment of corn and the explosive increase in soybeans and in rice acreages display significant shifts in cropping patterns. The decline in corn accompanies the abandonment of the mule technology and the shift of land to the profitable cash crop, soybeans. The sharp break in the explosive adoption of rice is associated with the imposition of federal controls in 1955.

The pattern of technological change *derived from the model* is shown for cotton and corn in Figure 2. Because Stage III technology was introduced in the model in 1945, while in fact it was started in the 1930s, the pattern for Stage II cotton production shows a discontinuity at 1946 that would be eliminated by correcting the initial conditions. The model also exaggerates the adoption of cotton Stage IV after 1954. This is due to an oversimplification of the investment process. But these are errors of detail that do not modify the story of rapid adoption of new technique and rapid abandonment of the old.

Stage I, we recall, is the most labor and mule intensive set of techniques and is associated with the sharecropper tenure system. Roughly speaking one sharecropper family and one or two mules provided the power for a fifteen acre unit of a larger farm or plantation [5] [8]. The abandonment of the Stage I technology in favor of Stage II and Stage III indicates a decline, therefore, in the sharecropper system and a shift to wage labor supplied by resident, former sharecropper families, or by workers transported to the farm from neighboring villages.

Productivity is measured in various ways, but because in the present paper we are concerned with the effect of technological change on the derived demand for labor, it is particularly useful to show productivity in terms of labor input per unit of physical output. Actual input-output ratios change randomly from year to year as yields respond to the capricious movements of weather. To eliminate these deviations we have

¹¹ For a more complete presentation and critique of the model tests see [3, pp. 117-41]. A statistical theory of hypothesis testing is not available for recursive programs. Still a systematic comparison of model estimates with data has been performed.

Cotton

Corn

FIGURE 2. MODEL ESTIMATES OF THE ADOPTION OF NEW TECHNOLOGY AND THE ABANDONMENT OF OLD TECHNOLOGY

used the "average" yield coefficients of the model.¹² Also the contribution of each alternative way of producing cotton is included, weighting each by its corresponding process level as estimated by the model.

The ratios thus derived for cotton and corn are illustrated in Figure 3. Separate indexes for skilled and unskilled labor and the numerical counterpart of Figure 3 are presented in Table 1. They display declining ratios for unskilled labor and rising ratios for skilled labor. But the average effect, due to the vastly higher productivity of the skilled labor, is a sharply declining overall trend in the input-output ratios, as shown in the figure. It incorporates both shifts to labor saving technology and to higher levels of fertilization.

Total labor requirements in manhours per unit of output.

FIGURE 3. TRENDS IN AVERAGE LABOR REQUIREMENTS. DERIVED FROM THE MODEL.

III. *The Derived Demand for Labor and the Two Stage Push off the Farm*

The flow of investment into new production techniques implies a changing composition of labor demand. The trends in regional farm labor requirements, estimated by the model, are presented in Table 2. They include the utilization of "unskilled" labor, the use of "skilled" labor (tractor drivers plus special machine operators), and the trend in total utilization of labor of both kinds.

These show the combined effects of changes in machine technology, in fertilizer usage, and in cropping patterns. The effects of the first and last of these items are to reduce labor requirements, the first by substituting capital-intensive for labor-intensive techniques; the last by substituting labor saving for labor intensive crops—primarily soybeans for cotton and corn. The second item, increased fertilizer usage, tends to

¹² For the estimation of average yields see [3, pp. 75-80, 175-84].

TABLE 1—AVERAGE LABOR INPUT PER UNIT OF OUTPUT ESTIMATED BY THE MODEL

| Year | Cotton (hrs./cwt.) | | | Corn (hrs./bu.) | | |
|------|--------------------|---------------|-------|-----------------|---------------|-------|
| | Unskilled Labor | Skilled Labor | Total | Unskilled Labor | Skilled Labor | Total |
| 1940 | 33.5 | .32 | 33.82 | 1.2 | .20 | 1.40 |
| 1941 | 33.0 | .36 | 33.36 | 1.1 | .20 | 1.30 |

| 1951 | 8.4 | 1.64 | 10.04 | 1.0 | .37 | 1.37 |
| 1952 | 3.0 | 1.82 | 4.82 | 1.3 | .10 | 1.40 |
| 1953 | 5.2 | 1.91 | 7.11 | 0.8 | .30 | 1.10 |
| 1954 | 4.5 | 1.89 | 6.39 | 0.7 | .33 | 1.03 |
| 1955 | 4.0 | 2.02 | 6.02 | 0.7 | .10 | .80 |
| 1956 | 3.1 | 2.29 | 5.39 | 0.4 | .23 | .63 |
| 1957 | 2.4 | 2.50 | 4.90 | 0.3 | .20 | .50 |

cancel some of the downward spiral in labor demand by raising cotton and corn yields per acre and thus increasing per-acre labor requirements for cotton and corn picking. But as hand labor is replaced by mechanical harvesting techniques this effect also declines in importance.

The implications of these patterns for farm organization may best be viewed by considering the contrast with agriculture outside the south. Labor demand in middle-western agriculture is predominantly satisfied by the "farm operator." That is, management and labor are combined. But the tenure pattern in the deep south at the beginning of our period displayed a quite different arrangement. Here the farm operator participated, if at all, only in the mechanized phases of the work. He reserved the remainder of his time for supervising the plantation's portion of the sharecropper's work and attended to the financial aspects of the plantation as a whole.

As a result of technological change this pattern changed radically. The operator himself more and more participated in the work of his now predominantly mechanized enterprise. His decision to invest in machinery also meant a decision to change the status of the sharecropper. The full effect of this pressure cannot fully be appreciated, however, without a look at still another aspect of the region's farm technology: seasonal distribution of labor requirements.

During the early parts of the 1939-1957 period the shift to labor

TABLE 2—FARM LABOR REQUIREMENTS IN THE MISSISSIPPI DELTA
ESTIMATED BY THE MODEL (millions of man hours)

| Year | Unskilled Labor | Skilled Labor | Total Labor |
|------|-----------------|---------------|-------------|
| 1940 | 170.2385 | .6908 | 170.929 |
| 1941 | 168.0305 | .7330 | 168.764 |

| 1955 | 25.0885 | 1.6628 | 26.751 |
| 1956 | 17.5346 | 1.8570 | 19.392 |
| 1957 | 13.6818 | 1.9334 | 15.615 |

saving technology did not drastically reduce peak season labor demands. Rather it began a radical shift in its seasonal distribution. Stage II technology, for example, eliminated the mule-powered land preparation and cultivation activities. Stage III further reduced hand labor requirements and also mechanized labor requirements, the latter through adoption of larger scale equipment, the former through advancements in the use of flame throwers and herbicide applicators. But only after considerable investment in Stage IV technology took place, did the labor demand during cotton harvesting season decline for technological reasons.¹³ The basis for this seasonal effect is found by examining the average unskilled labor-time distribution functions shown in Figure 4. One can see that the consequence of adopting Stages II and III was to eliminate virtually all hand labor except for the summer weeding and fall harvesting seasons. This meant that the maintenance of sharecroppers the year round became uneconomic. Instead, a combination of resident wage labor and labor hired from nearby villages was favored. The implications for changing social structure are clear.¹⁴

¹³ The labor demand did fall during the 1950, 1954-57 years because of cotton production allotments.

¹⁴ A similar phenomenon will surely be encountered in other developing areas and industries that have quite asymmetric seasonal labor requirements. Seasonal unemployment—or in the aggregate, disguised unemployment, may very well be aggravated by technological advances that increase both output and peak season employment in the region or industry.

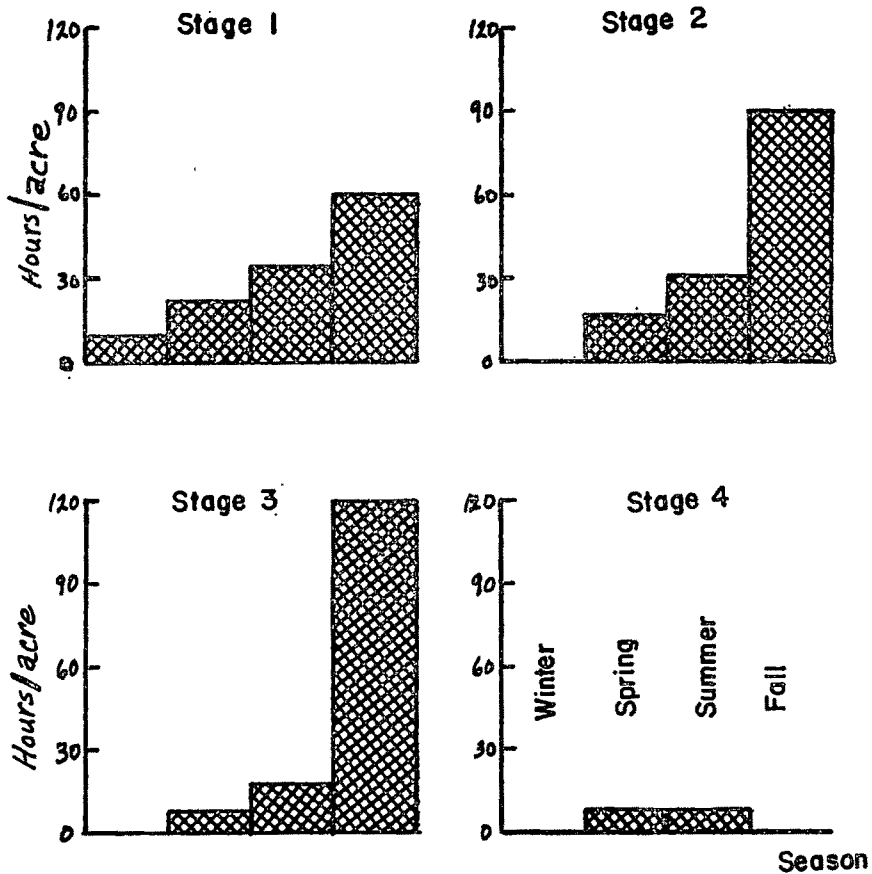

FIGURE 4. SEASONAL DISTRIBUTION OF UNSKILLED LABOR DEMAND IN COTTON PRODUCTION BY STAGE OF TECHNOLOGY.

But before we describe the implied two-stage push of labor off the farm we must take up one further technicality that was not included in the basic model description above. This item is a peculiarity of the model structure that identifies bottleneck and surplus resources. If one of the various constraints of the model is "equated" or "tight" it implies that more of the corresponding resource could be profitably used at current expected prices. If the constraint is "slack" or "loose," the opposite condition is implied.

The implications of this feature in the present analysis are that a declining resource that is "tight" is not being replaced at a rate sufficient to meet demand or, alternatively, it is being "pulled out" of the sector altogether. On the other hand, if the resource is "loose" it is a surplus item, and, if there is some cost to maintaining the surplus, it

is likely to be "pushed out" of the sector. During the recent history investigated here unskilled, harvest period (September-December) labor exhibited both categories [3, pp. 215]. This is shown in Figure 5.

During the war and immediate postwar era labor shortages were felt everywhere. After the war the increase in cotton acreage raised the derived demand for labor faster than the adoption of labor saving techniques lowered it. During this period the model shows that labor was a "tight" resource. But very soon, as the adoption of Stage III and IV methods accelerated, it lost this status, so that from 1941 to 1949 labor is a bottleneck but after that date it becomes a surplus commodity—even at the pitifully low wage rates in existence at the time.¹⁵

FIGURE 5. THE DERIVED DEMAND FOR UNSKILLED LABOR IN DELTA AGRICULTURE. Solid lines show year of labor "shortage." Dotted lines show year of labor "surplus."

Thus, without looking at migration data at all, it is possible to infer from the dynamic production model that during the first half of our period the labor released by mechanization was at least partially absorbed by the burgeoning economy in the industrial centers of the south and north. After that time external growth in demands for displaced sharecroppers was too sluggish and one may infer that such migration as may have occurred was induced more by a push than by a pull effect.

It is here that the consideration of seasonal labor distribution is important. For the early stages of technological changes were not associated so much with a push of sharecroppers out of the region (because

¹⁵ Wage rates in 1949 were roughly 32¢ per hour. They hit a 1940-58 peak in 1951 of about 40¢ per hour [3, p. 210]. Data are not included here to show the annual income of wage earners in the class we are considering but \$500 per year would not be at the lower end of the wage earners income range. It seems to me unlikely that still lower wages would have moved the surplus faster than its already rapid rate of exodus.

TABLE 3—DECILE POPULATION DATA

| Population | Delta | | | Mississippi | | | United States | | |
|---------------|-------------|------|------|-------------|------|------|---------------|------|------|
| | 1940 | 1950 | 1960 | 1940 | 1950 | 1960 | 1940 | 1950 | 1960 |
| | (thousands) | | | (thousands) | | | (millions) | | |
| Rural Farm | 316 | 257 | 119 | 1400 | 1097 | 543 | 30 | 23 | 13 |
| Rural Nonfarm | 51 | 66 | 128 | 351 | 475 | 814 | 27 | 31 | 40 |
| Urban | 63 | 87 | 121 | 433 | 607 | 821 | 74 | 96 | 125 |
| Total | 430 | 410 | 368 | 2184 | 2179 | 2178 | 131 | 150 | 178 |

of the remaining harvest season peak labor demands), so much as they were associated with a push of sharecroppers off the farm itself (where they had to be maintained year around) to the village (where they provided a conveniently located labor pool that could be inexpensively transported to surrounding plantations and farms).

To summarize, the peak harvesting season handwork load declined only with the adoption of technology Stage IV. It was this peak season load that formerly kept the agricultural worker in relatively short supply—even as he became increasingly urbanized. With this last vestige of economic livelihood rapidly dwindling, there occurred the second-stage push of labor out of the agricultural sector altogether and out of the region in search of some other way of life.

IV. *Population Effects*

If the two-stage push is a correct inference from the model, its effects should be reflected in population movements. We should observe a shift of people from a rural farm to a rural nonfarm status as a result of the first-stage push off the farm. Sharecroppers formerly classified as farmers become rural nonfarm workers as they move from a share-tenure arrangement to a wage-labor status either on the farm or in the villages and small towns. As a result of the second-stage push we should observe a movement of population from the rural to the urban sector and this should be reflected in a population increase in the cities or by a decrease in population in the region as a whole.

While a related ecological study cannot be pursued here in any great depth, a brief consideration of census data should provide a useful check on the analysis. Tables 3 and 4 present decile census data for the Mississippi Delta Area, the State of Mississippi, and the United States as a whole, the former in absolute numbers of people and the latter in percentage changes 1940-50, and 1950-60, 1940-60.

It seems to me there can be little doubt that the two-stage push occurred more or less as the model described it though it is worth re-

TABLE 4—RELATIVE POPULATION CHANGES

| Population | Delta | | | Mississippi | | | United States | | |
|--|---------|---------|---------|-------------|---------|---------|---------------|---------|---------|
| | 1940-50 | 1950-60 | 1940-60 | 1940-50 | 1950-60 | 1940-60 | 1940-50 | 1950-60 | 1940-60 |
| Rural Farm | -19 | -54 | -62 | -22 | -50 | -62 | -23 | -43 | -56 |
| Rural Nonfarm (Cities 2500 or less) | +30 | +93 | +151 | +35 | +71 | +132 | +14 | +29 | +48 |
| Urban (Cities over 2500) | +38 | +39 | +90 | +40 | +35 | +89 | +30 | +30 | +67 |
| Total | -5 | -10 | -12 | 0 | 0 | 0 | +14 | +19 | +34 |

membering that both push effects occurred to some extent at the same time. That is, some farms were in the second-stage push (caused by the adoption of Technology Stage IV) while others were still in the first (caused by the shift to Technology Stages II and III from the Sharecropper Stage I).

It is also important to remember that the census data only measure numbers of people in a given year. Because intervening births and deaths are not reflected in the figures, they only indicate a lower limit on the net flow of people from one sector to another. No doubt the migration was considerably more intense.

V. *Summary and Conclusions*

An economic model of production, investment, and technological change has been described that was tested using data for the Mississippi Delta farm economy. It included regional endowments of land resources, the response of yields to commercial nutrients, alternative cropping enterprises, and production techniques. Guided by the traditional profit maximizing theory of economics, the model explains how the interaction of geographic, biological, technological, and economic forces led in this region to a history of advances in productivity and declines in labor requirements at a revolutionary rate; how in fact within a generation the economic structure and social life of the region underwent a complete transformation.

The results, perhaps modified for differences in timing and technological detail, are reasonably representative of southern agriculture and even to some extent of U.S. agriculture as a whole. It also seems likely that the economics of technological change in other industries is similar and has equally significant implications. Studies involving investigations of several nonagricultural industries using similar methods are now under way in order to explore this possibility.

MATHEMATICAL NOTES

In this appendix the mathematical form of the analysis is outlined in the order followed in the text.

Production Processes, and Input, and Output Matrices

Let P_{hijk} be a production process for the h^{th} crop combination using the i^{th} technological stage on the j^{th} soil type at the k^{th} fertilizer level. Let x_{hijk} be the intensity measured in acres at which this process is operated, y^m_{hijk} be output coefficient (per acre yield) of the m^{th} output commodity and a^n_{hijk} be the input requirement of the n^{th} variable input. Here m ranges over nine output commodities and n ranges over 36 variable inputs including labor, power, machine operation and materials items. Arranging these items in a vertical list we obtain a 9-element output coefficient vector g_{hijk} , say, and a 36-element input coefficient vector a_{hijk} , say, for each of the 103 processes P_{hijk} . These may be stacked side by side to give the 9 by 103 Output Coefficient matrix G , say, and a 36 by 103 Input Coefficient matrix A , say.

This formulation allows for joint production such as would occur in fixed rotation programs. In the present model only part of the processes have this property. Cotton-lint and cotton seed are outputs of all cotton processes so that two positive yield coefficients appear for these. There are also some cotton processes that use mule powered draft operations in which both cotton and corn are produced. In these columns, three yield coefficients are greater than zero. This form enables one to account in a simple manner for the almost fixed complementarity between the production of cotton using mule power and the production of corn to feed mules.

Net Return and the Profit Objective

Let $p(t)$ be a 9-element vector of output prices in time t corresponding to the nine output commodities and $q(t)$ a 36-element vector of input prices at time t corresponding to the 36 input prices. Let $z(t)$ be a 103-element vector of unit process return where z_{hijk} is the net return of the process P_{hijk} . Then we have

$$z(t) = G^T p(t) - A^T q(t)$$

Expected net returns are assumed to be

$$\hat{z}(t) = z(t - 1)$$

Thus, for a given year they are assumed to be equal to what they would have been in the preceding year if the yield coefficients and variable input coefficients had been those used in planning. The profit or objective function that incorporates the goal of maximizing expected profits is

$$\pi(t) = \hat{z}^T(t)x(t)$$

Fixed Factor Constraints (land)

If \bar{x}_j is the regional supply of soil j then

$$\sum_{hik} x_{hijk} \leq \bar{x}_j$$

Quasifixed Factor Constraints (machine capacities)

The flows of services of the various stocks of quasifixed factors associated with a given technology are measured by either total acres of capacity or

total production capacity. In reality capacity in machinery utilization is considerably more flexible than this treatment indicates. At the regional level of aggregation, however, the distortion does not appear to be great.

Let $I_{hi}(t)$ be actual investment in the machine capacity of technological stage h for producing crop combination i , and let $C_{hi}^*(t)$ be the capacity actually utilized, and α_{hi} be a "maximum potential investment coefficient." Then

$$I_{hi}(t) \leq \alpha_{hi} C_{hi}^*(t)$$

Suppose the amount of capacity utilized by a given process is given by the "capital utilization coefficient" b_{hijk} and $x_{hijk}^*(t)$ is the process level in year t then

$$C_{hi}^*(t) = \sum_{jk} b_{hijk} x_{hijk}^*(t).$$

Now by definition $I_{hi}(t) = C_{hi}^*(t) - C_{hi}^*(t-1)$ so that

$$\sum_{jk} b_{hijk} x_{hijk}(t) \leq (1 + \alpha_{hi}) \sum_{jk} b_{hijk} x_{hijk}^*(t-1)$$

The investment parameters " α_i " are really behavioral coefficients that describe the rate at which farmers in the region are willing and able to invest in quasifixed factors, a rate that depends upon growth in knowledge about previously unused machines and upon the rate at which quasifixed factors can be supplied by the industries producing them.

Labor and Fertilizer

In the text labor and fertilizer were considered to be quasifixed factors at the regional level. This treatment rests not on the durability of these inputs but rather on three separate considerations related to firm behavior. One is the effect of money capital, another is growth in knowledge, and a third, imperfect knowledge of supply-price relationships. Money capital is not treated explicitly in this model, but its constraining influence is felt in the region due to the frequent practice of financing production expenses and investment capital. This influence is felt particularly on the purchase of labor and fertilizer which comprise a large part of production expenses in the region. In the case of fertilizer, knowledge about the benefits of increasing intensity of utilization has accumulated steadily. Demand for its use has correspondingly risen with this knowledge. Finally, and quite surprisingly, individual farmers may face a rising supply curve for labor. That is, farmers may restrict their purchase of labor services at existing (perhaps economical) prices because they may expect that to acquire more they would have to pay an uneconomic price. This phenomenon most probably is caused by emigration of unskilled labor from rural areas to neighboring towns. Costs of transporting labor back to the farm raises its price. It is also caused by net emigration out of the region altogether. The supply curve for labor to the firm has probably receded over time due to emigration, and its price elasticity over relevant ranges has probably decreased due to transportation costs.

Unable to develop explicit models of supply for these factors, we treat the

total potential utilization of these inputs as exogenous trends, falling in the case of labor and rising in the case of fertilizer utilization. If ℓ and f are the input indexes of labor and fertilizer respectively for the production process represented by indexes $hijk$, then

$$\sum_{hijk} a_{hijk}^m x_{hijk}(t) \leq k_m(t), \quad m = \ell, f.$$

Where $k_\ell(t)$, $k_f(t)$ are exogenously determined trend values in total potential utilization of labor and fertilizer respectively in the region.

Uncertainty (Flexibility) Constraints

Let $\bar{\beta}_i$ be an "upper flexibility coefficient" and β_i be a "lower flexibility coefficient" for the i^{th} crop combination. Then

$$\begin{aligned} \sum_{hjk} x_{hijk}(t) &\leq (1 + \bar{\beta}_i) \sum x_{hijk}^*(t-1) \\ - \sum x_{hijk}(t) &\leq - (1 - \beta_i) \sum x_{hijk}^*(t-1). \end{aligned}$$

Here the flexibility of increasing or decreasing the acreage of a crop is found above and below by certain percentage changes over the preceding year.

One may ask how these behavioral constraints can in any sense reflect real behavior. One finds the answers in farmers' imperfect knowledge of demand for their outputs. Farmers are well acquainted with the fact that if aggregate supplies of their commodities increase, prices received will fall. But they cannot know in advance what aggregate supplies will be, not only because of weather, but also because they cannot forecast the behavior of all other producers. Therefore, they are cautious in changing their production patterns in response to current profit expectations.

Acreage Allotments

Let $a_i(t)$ be the allotment in year (t) for the i^{th} crop or if there is no allotment set $a_i(t) = \infty$. Then

$$\sum_{hjk} x_{hijk}(t) \leq a_i(t)$$

Summary of Constraints

The various constraints given above can be summarized by the following constraint notation

$$Bx(t) \leq \Gamma Bx^*(t-1) + k(t)$$

in which the rows of B correspond to the various constraints and contain the zero, one, or b or " $b_{ijk\ell}$ " coefficients contained in them, and in which the diagonal elements of the Γ coefficients are zero for the fixed factors, exogenous variable factors and allotments and otherwise are the $1+\alpha$ or $1\pm\beta$ coefficients of the investment and uncertainty constraints, all nondiagonal elements being zero.

The Recursive Programming Formulation

From the above we may form the following dual recursive programming problems.

$$\pi^*(t) = \max_{x(t)} [G^T p(t-1) - A^T q(t-1)]^T x(t)$$

subject to

$$Bx(t) \leq \Gamma B^*(t-1) + k(t),$$

and

$$\rho^*(t) = \min_{r(t)} [\Gamma Bx^*(t-1) + k(t)]^T r(t)$$

subject to

$$B^T r(t) \geq G^T p(t-1) - A^T q(t-1).$$

The model has initial conditions $x(1939)$ and exogenous variables $p(t)$, $q(t)$ and $k(t)$, $t=1939, \dots, 1958$. The model is solved recursively for $t=1940, \dots, 1958$.

Derived Supply of Agricultural Outputs

Let $Y(t)$ be the vector of estimated supplies of agricultural commodities of the region. Then

$$Y(t) = Gx^*(t), \quad t = 1940, \dots, 1958.$$

Derived Demand for Agricultural Inputs

Let $V(t)$ be the vector of estimated derived demands for inputs, then

$$V(t) = Ax^*(t), \quad t = 1940, \dots, 1958.$$

In particular, among the elements of $V(t)$ are the derived demands for labor by type.

Productivity Indexes

Let

$y_m(t)$ be the output of the m^{th} commodity at time t .

$$\text{Then } Y_m(t) = \sum_{hijk} y_{hijk}^m x_{hijk}^*(t)$$

Let

$V_n(t)$ be the input of the n^{th} input at time t .

$$\text{Then } V_n(t) = \sum_{hijk} a_{hijk}^n x_{hijk}^*(t)$$

Then the average input/output ratio is $V_n(t)/Y_m(t) = \phi_{nm}(t)$.

Or if one wants an average input/output ratio derived for several inputs we have

$$\phi'_{nm}(t) = \sum V_n(t)/Y_m(t)$$

where the summation is over some range of n .

Seasonal Distribution of Labor

Let γ^s_{hijk} be coefficients describing the time distribution of labor requirements for the given process. Then

$$\gamma^s_{hijk} a^n_{hijk} = a^{ns}_{hijk}$$

would give the requirement of input n during time subperiod s for process P_{hijk} .

By appropriate constructions these coefficients could be used to derive the seasonal distributions of labor (or any other input) demand as a function of time that depended on the derived process levels $x^*(t)$. This changing pattern would therefore be related to all the components of the model.

THE SHORT RUN REVISITED

By LOUIS DE ALESSI*

The theory of the firm has been the subject of voluminous literature. Nevertheless, some ambiguities and inconsistencies still persist. In particular, the traditional approach to the short run as a period in which the quantities of some inputs cannot be varied¹ requires clarification. The failure to recognize explicitly that the adjustment of a firm to a change in market conditions depends upon the costs and receipts associated with the adjustment leads to a number of ambiguities, including some confusion regarding the regions of the production function that are empirically relevant.

Section I contains a brief statement of the traditional short-run theory of the firm; then, as a first approximation, the main implications regarding the paths of prices and of input proportions in the short run are derived from higher-level economic hypotheses. Section II indicates how the relevant predictions regarding the short-run behavior of the firm may be derived from the wealth-maximizing (stock) approach, avoiding some shortcomings of the traditional profit-maximizing (flow) approach. Section III extends the analysis to the "uneconomic" regions of the production function. Section IV contains a few concluding remarks.

I

Consider a competitive firm whose production function²

$$(1) \quad Z = f(a_1, a_2)$$

is hypothesized to be a single-valued, continuous function with continuous first- and second-order partial derivatives; all variables represent flows per unit time.³ The parameter Z° defines a particular output isoquant, conforming to the usual requirement, with slope at a point equal to $-f_1/f_2$.

Let the firm purchase inputs a_1 and a_2 in perfectly competitive markets at constant prices p_1 and p_2 . Total costs of production are given by the linear equation:

$$(2) \quad C = p_1 a_1 + p_2 a_2,$$

* The author is associate professor of economics at Duke University. He acknowledges helpful comments by D. G. Davies, C. E. Ferguson, and J. S. McGee.

¹ For example, see [11, p. 41].

² The following exposition, equations (1) through (3), is standard in the literature. For example, see [6, Ch. 3].

³ The traditional production function relates rates of input utilization to rates of output. As A. A. Alchian [1] has suggested, however, planned volume (V) of output may be a crucial variable; this point, together with some shortcomings of the flow relative to the stock approach in the analysis of the firm, will be examined in subsequent sections of this paper.

and the parameter C° defines a particular isocost with constant slope equal to $-p_1/p_2$.

Well-known first-order conditions for cost minimization subject to an output constraint require that the input-output combination be on the locus of points (least cost path) where:

$$(3) \quad \frac{f_1}{f_2} = \frac{p_1}{p_2},$$

that is, where the ratio of the marginal products of the inputs is equal to the ratio of their prices.⁴ In Figure 1, the least cost path is shown by OE .

FIGURE 1

Given the output demand function, the long-run equilibrium conditions for a profit-maximizing firm are easily obtained. Traditional statements of the theory then turn to the main problem at hand, the response of the individual firm to changes in circumstances (e.g., an increase in the demand for the output of the firm) that disrupt the equilibrium.⁵ Let T measure the period from the instant of time some disturbance occurs to the instant of time a given adjustment is completed, where the

⁴ Fulfillment of second-order conditions implies that output isoquants are concave from above over the relevant range [6, p. 51].

⁵ For the sake of brevity, the analysis in this paper is usually limited to the consequences associated with an increase in the demand for the output of the firm. The analysis, however, can be easily extended to include the consequences of a decrease in demand, of changes in the input supply function(s), and of changes in the firm's production function due to technological innovations.

adjustment may involve a change in input proportions as well as a change in the absolute quantity and in the form of the inputs utilized. The usual procedure is to consider adjustment periods or runs of progressively longer duration, where the longer the run, the more inputs the firm "can" vary and the greater the variation permitted in the quantity of any given input. In the two-input case, one short run may thus be shown by holding a_2 fixed at the initial equilibrium level (e.g., point 1 in Fig. 1) and allowing a_1 to vary.

The purpose of distinguishing between runs of different length presumably is to explain the empirical observations that, the shorter the period T , the higher is the cost of the change in output and the fewer the inputs that are varied. It follows that economic theory, *inter alia*, must yield implications consistent with this evidence. By defining the short run as the time period in which some inputs cannot be varied, the desired implications regarding costs are obtained, e.g., [5, pp. 111-15]. This solution, however, avoids a crucial theoretical issue. Implications regarding the proportions in which factors are varied in a given market situation must also be derived from the theory. In particular, the statement that some inputs are held fixed during a given period must be interpreted as a falsifiable proposition implied by economic theory. The phenomenon in question may be identified (defined) as a short run, but the definition in no sense substitutes for the hypothesis.

All factors of production are variable over any given time interval greater than zero. The rate at which different inputs in fact are varied over time in response to some change in market conditions must depend upon the relative costs and receipts of all the alternative production strategies technologically available to the firm.

As a first approximation, hypothesize that the closer an output program is moved to the present (the shorter the period T) the greater are the costs [1]. Applied to the sellers of the inputs, this proposition implies that as shorter T 's are considered the input supply curves decrease (shift to the left) and the greater is the cost to the buyer of varying any given input. That is,

$$(4) \quad p_i = p_i(T), \quad p'_i < 0, \quad (i = 1, 2);$$

substituting⁶ into equation (3) yields:

$$(5) \quad \frac{f_1}{f_2} = \frac{p_1(T)}{p_2(T)}.$$

⁶ Although the analysis developed in this paper is not dependent upon the validity of the following conditions, it may be presumed that eventually $p'_i = 0$, and that $p''_i > 0$ over at least part of the interval where $p'_i < 0$.

Equation (4) does not deny that each firm purchases its inputs competitively. The input supply curve facing the individual firm is still hypothesized to be perfectly elastic at the price associated with a particular T ; however, the shorter the period the higher is the price intercept.

As shorter periods T are considered, not only do supply functions decrease, but the rates of shifting differ among at least some of the inputs. The ratio $p_1(T)/p_2(T)$ increases, remains the same, or decreases depending upon whether the rate of change in p_1 with respect to T is greater than, equal to, or less than the rate of change in p_2 with respect to T (in all cases, all isocosts shift to the left as shorter T 's are considered).

Each firm is thus hypothesized to consult a family of sets of budget constraints, where each set contains all possible alternative budget constraints of a given slope associated with the particular run contemplated by the firm for the (possibly partial) adjustment. Presumably one family of sets is applicable to expansion and another is applicable to contraction. Given the iso-product map derived from the traditional production function, a least cost path exists for each input price ratio associated with each adjustment period T . Each short-run least cost path is discontinuous at the original equilibrium point (e.g., $1E^\circ$ in Fig. 1), since the firm presumably can continue to produce the current output at the current least cost.

Each short-run least cost path yields a short-run total cost curve. If diminishing returns prevail, the total cost curve (TC) for an increase in output during a particular short run T° would be similar to TC° in Fig. 2.⁷ The longer the adjustment period T , the closer the short-run total cost curve approaches the long-run TC . Thus, the long-run TC (e.g., TC in Fig. 2) is the boundary of all the short-run TC curves.

Economic theory also asserts that the shorter the time interval, the smaller is the price elasticity of the market demand for a commodity. Thus, even in the case of a firm selling its output under purely competitive conditions, different output prices will prevail during at least some of the different adjustment periods considered by the firm. The form of the function relating the demand price per unit of output to T presumably has the same general properties attributed in equation (4) to the input price functions. It follows that a unique total revenue curve and a

⁷ Note that the behavior of the individual firm is at issue. Thus, the *schedule* of input prices (where each price relates to a particular "run") is impounded in *ceteris paribus*. If expansion or contraction of all firms in the industry affects the schedules of input prices (input supply functions facing the industry are not perfectly elastic), then the firm's cost curves will shift accordingly.

The discontinuity in TC° is associated with the approximation developed in this section and the two-dimensional nature of the diagram. A more complete statement of the appropriate cost surface is presented in Section II.

unique total cost curve may be associated with each run,⁸ and the usual criteria may be used to derive the profit-maximizing program for each period.

The analysis developed in this section implies that the firm is induced to seek full adjustment over time rather than instantaneously, and to vary inputs in different proportions as longer T 's are considered. In particular, the firm may *choose* to hold one or more inputs fixed during periods of partial adjustment. For example, suppose that a firm initially

FIGURE 2

is producing under conditions of long-run equilibrium (e.g., point 1 in Figs. 1 and 2), and that the demand for its output increases. Given the elasticity of this demand over time and the family of all short-run relative input prices, the profit-maximizing program during a particular short run may be that associated with the input price ratio shown by I'_2 (Fig. 1), and with point 2 (Figs. 1 and 2) in particular. In this event, the firm would choose to hold a_2 fixed for a time. The long-run equilibrium output, for an unchanged *schedule* of input prices, would still be along OE (e.g., point 4 in Figs. 1 and 2). It should be noted that, in the absence of any information regarding the relative costs of varying inputs

⁸ This approach yields the familiar implication that firms will specialize in the speed (time elapsed) of their responses to changes in market conditions.

in different proportions over different time periods, there is no a priori reason for predicting which factor, if any, will be held constant.⁹

It seems generally recognized that adjustment to a change in market conditions is not a free good. So far, the main assertion contained in this paper is that the extent of the adjustment depends upon the relevant costs and receipts. The traditional statement that the quantities of some inputs cannot be varied in the short run implies a denial of the higher-level economic hypotheses that demand curves are negatively sloped (the lower the cost of changing the input mix, *ceteris paribus*, the quicker the full adjustment) and that supply curves are positively sloped (the quicker the full adjustment sought, *ceteris paribus*, the higher the cost of changing the input mix).

Similarity with traditional analysis, however, has been maintained by choosing the particular set of isocosts associated with a particular run, relating the short-run least cost path to the price per unit of output associated with that run, and identifying the profit-maximizing input-output combination.

II

The isoquant-based theory of the firm yields decision rules in terms of flows: under long-run competitive equilibrium, at the margin the rate of expenditures on all inputs is equal to the rate of receipts from the sale of the output, where presumably the rates in question remain constant indefinitely. When a disturbance occurs, *ceteris paribus*, the new long-run equilibrium flows may be derived and used to predict the long-run response of the firm. Under these circumstances, the present value of the constant rate of outlay given by each isocost and the present value of the constant rate of receipts associated with each output isoquant will yield present value total cost and total revenue curves with the same shape as the total cost and the total revenue curves given by the profit-maximizing model of traditional theory. Thus application of the usual marginal rules to the stock (wealth) and to the flow (profit) models would yield the same predictions regarding the long-run behavior of the firm. As Alchian and others have emphasized, however, the crucial concept is the *wealth* effect of the alternative strategies considered by the firm; this must be so, since the firm can always alter the time pattern of the flows by either lending or borrowing.

During the process of adjusting to a given disturbance, the pattern of flows for a given firm may be expected to vary from period to period.

⁹ This conclusion does not seem to be inconsistent with observation. Without allowing empirical evidence to intrude, it might be granted that in some cases the short-run cost of varying the quantity of some types of labor is greater than the cost of varying some types of plants or equipment, while in other cases the opposite cost relationship prevails. For an example of empirical evidence inconsistent with the classical treatment of labor as a purely variable factor, see [9].

Predictions regarding the behavior of the firm in the (traditional) short run are usually obtained by examining progressively longer "representative" short runs of unspecified duration. Similarly, the short-run least cost paths derived in the preceding section may be useful pedagogically in deriving implications with respect to the nature of the short-run cost curves, and, in addition, to the short-run changes in input proportions. However, it must be recognized that the decision of the firm to adopt a particular input-output program during a particular time period can only be predicted by discounting to the present the flows associated with the alternative input-output programs for different periods, and then choosing the wealth-maximizing sequence of programs. That is, a rational firm must consider a multiperiod horizon in determining the input-output rates in a specific period; in particular, a firm owning resources must decide the intertemporal allocation of such resources.

A firm responding to a change in market conditions may be viewed as producing the adjustment involved in addition to the other product (Z) under consideration. The present value cost, C_p , of the adjustment may be hypothesized to be a function of (1) x , the rate at which the adjustment is undertaken, (2) V , the total planned adjustment, (3) T^* , the length of the interval between the time when the disturbance occurs and the time when the adjustment is begun, and (4) m , the length of the interval between the time when the adjustment is begun and the time when the adjustment is completed:¹⁰

$$(6) \quad C_p = f(x, V, m, T^*), \quad C_p \geq 0, .$$

where $f_x > 0$, $f_{xx} > 0$, $f_V > 0$, $f_{VV} < 0$, $f_{xV} < 0$, $f_{T^*} > 0$ [1]. The total quantity of the adjustment undertaken and its schedule over time would then be determined at the margin in conjunction with the present value of the receipts from the adjustment. In this construct, the long run may be defined as the time period in which deferred changes in the quantity (and form) of each input used by the firm would not lead to a lower input price to the firm in present-value terms.

That is, the individual firm is hypothesized to adjust the quantity and the form of each input it uses until the present value of the marginal stream of outlays is equal to the present value of the marginal stream of receipts for each input. The firm chooses the least-cost mesh of the alternative input adjustments subject to a set of output constraints related to the elasticity over time of the demand for the firm's output. The wealth-maximizing solution thus yields the total planned change in the quantity and form of each input, the rate at which the change is under-

¹⁰ The T^* used in this paper corresponds to the T used by Alchian [1]. Following Alchian, m is a dummy variable whose value is determined by the values assigned to x and to V , where $V = \int_{T^*}^{T^*+m} x(t) dt$ and x may vary over time.

taken, the instant of time when the change is begun, and the time period taken to complete it.¹¹ *Inter alia*, this approach yields information regarding the time period during which a specific input is held fixed and the schedule at which each input adjustment is phased into the production process.

The procedure outlined in the preceding paragraph would yield one point on the (flow) iso-product map for each period. The input-output program presumably will vary from period to period as the firm completes its adjustment, and may involve holding the rate of utilization of one or more inputs fixed during a given time period.¹²

These comments suggest that a particular input-output combination may appear to be irrational in terms of the flows prevailing in that period, and yet be the rational choice in terms of the wealth-maximizing model. Put more strongly, the flows prevailing in one time period do not provide, by themselves, sufficient information to determine the choice of the output program for that period [1]. Economists have obtained propositions regarding the short-run behavior of the firm from a model designed to predict long-run behavior under constant flows, but they have done so only at the cost of ignoring some relevant portions of economic theory.

III

The production function of a firm, according to one definition, "... shows the (maximum) quantity of product it [the firm] can produce for given quantities of each of the various factors of production it uses" [5, p. 123]. This definition has been taken to imply that a firm would not use additional quantities of a given input¹³ beyond the economic region;¹⁴ that is, output isoquants outside the relevant ridge lines would be straight lines parallel to their respective axes [3, p. 304]. A second definition of the production function rests on the minimum factor quantities necessary for given outputs. On this definition, the segments of the output isoquants outside the ridge lines are taken to vanish [3, p. 304].

¹¹ In the case of one type of labor, for example, the present value of the hiring and training costs would be related to the planned number of workers to be added to the labor force, the rate at which such individuals are to be hired and trained, and the instant of time when the hiring and training programs are to begin.

¹² J. Hirshleifer has suggested that a firm may choose to hold some inputs fixed in the short run because of uncertainty regarding the permanence of the initial disturbance [7, p. 250]. The argument developed in this paper, although reinforced by the introduction of uncertainty, suggests that some inputs may be held fixed under conditions of certainty.

¹³ As M. Friedman has pointed out, however, this presumes that the cost of discarding some units of this input is zero [5, pp. 130-131].

¹⁴ The economic region is frequently defined (Rule I) as the range over which the marginal products (*MP*) of all inputs are greater than zero (and, possibly, equal to zero for some inputs); G. H. Borts and E. J. Mishan do so initially [3, p. 300]. Friedman [5, p. 130] and others,

Recently, Borts and Mishan have argued for a re-interpretation of the first definition. If a factor is taken to be fixed (and indivisible) during a given time period, and if the firm sells its output under monopolistic conditions, then output isoquants supposedly have meaning in the uneconomic region for the fixed factor and are straight lines parallel to the axis in the uneconomic region for the variable factor.¹⁵ Borts and Mishan conclude that "... it is logically inadmissible to construct a diagram in which in both uneconomic regions the iso-product curves are uniquely determined" [3, p. 307].

If "uneconomic" regions exist,¹⁶ the flow analysis developed in Section I of this paper implies that a firm would not operate within them.¹⁷

including Borts and Mishan later in the same article [3, p. 305], have noted that the maxim of rational behavior for a firm (Rule II) is to use such a combination of factors that the average product (AP) to each input separately is falling (or at least remains constant).

As Friedman and others recognize, these two rules yield the same answer only if the production function is homogeneous of degree one; then the locus of points (ridge line) where the AP of one input is maximum and the ridge line where the MP of the other input is equal to zero coincide. If the production function is homogeneous of degree less than one, then the ridge lines for AP maximum are outside the ridge lines for $MP=0$; if the production function is homogeneous of degree greater than one, the order of the ridge lines is reversed.

The two rules, of course, are not mutually exclusive. As Friedman concludes, "The point not to be exceeded is the point of vanishing (marginal) returns; the prudent man will seek to exceed the point of diminishing (average) returns" [5, p. 130].

If production functions are taken to be homogeneous of degree less than one, with degree one as the limit, satisfying the marginal conditions (operating in the range where the output isoquants are concave from above) is sufficient to insure that the AP of each input is either decreasing or constant.

Some economists, e.g., [10, p. 177], have suggested that the derivative of output, dZ (taken with respect to one of the inputs, when all inputs vary proportionately), first increases (increasing returns to scale) and then decreases (decreasing returns to scale). In the range of increasing returns to scale, application of rules I and II for rational behavior implies that the segments of the negatively sloped output isoquants outside the ridge lines for AP maximum would be in the "uneconomic" region of the production function.

Production functions yielding increasing returns to scale throughout are taken to be empirically irrelevant, since evidence purporting to support such functions has failed to allow for changes in the planned volume of output.

It may be useful to examine the form of the production function implied by Alchian's reformulation of the cost function. If planned volume (V) of output is held constant, the production surface with respect to the rate (x) of output exhibits decreasing returns to scale throughout. If the rate of output is held constant, the production surface with respect to V exhibits increasing returns to scale throughout. If V and x are taken to vary proportionately (the usual case, as suggested by Hirschleifer [7] and apparently accepted by Alchian [2, Ch. 21]), the production envelope at first exhibits increasing returns to scale and then decreasing returns to scale.

¹⁵ Borts and Mishan [3, p. 307] argue that (i) if both factors are indivisible in the short period, the firm is restricted to a point within the economic region; (ii) if both factors are variable during the period in question, all choices must fall within the economic region.

¹⁶ This paper is not concerned with the empirical question of whether "uneconomic" regions exist.

¹⁷ As noted earlier, second-order conditions for profit maximization imply that the firm would operate in the range where iso-product curves are concave from above. Moreover, a firm (at least a competitive firm) would operate beyond the region of increasing returns to scale if such a region existed.

Since it has been suggested that a noncompetitive firm using an "indivisible" factor may in fact operate in one of the uneconomic regions in the short run, the point deserves consideration.

The first issue to be examined is that of indivisibility.¹⁸ Why should a factor be indivisible in the short run? To take a standard example, consider a firm using tractors as one of the inputs. Following Friedman [5, pp. 131-32], suppose that tractors come in two sizes, with the tractor of size II being in some relevant sense "twice" the tractor of size I. Tractors presumably come in these two sizes, given the demand function for tractors, due to the lower unit cost associated with producing a larger planned volume of output (V) of each of the fewer models relative to the cost of producing a smaller V of each of a broader range of models [1]. A firm using tractors of size I, following some change such as an increase in the demand for its output, may well prefer to shift to an intermediate-size tractor at an intermediate price.¹⁹ If the cost of an intermediate-size tractor produced to order is sufficiently high, however, the firm may choose to acquire more of the standard sizes. That is, the choice to acquire some inputs in lumps can be predicted, at least in some relevant cases, by cost considerations alone. It may seem that this argument, if acceptable, applies to "indivisibility in acquisition" and not to "indivisibility in use" [8, pp. 231-33]. But "divisibility" of all inputs in acquisition implies "divisibility" of all inputs in use, since a firm, at some cost, may always choose to modify the structure of its assets or change the form of its inputs.²⁰ The theory must be capable of predicting the revealed choice of a firm in the short run, under specified circumstances, to vary some inputs in discrete quantities rather than in infinitesimally small quantities; it is not helpful to cloak in the name of indivisibility what is really a plea of ignorance.²¹

¹⁸ The term "indivisibility" has been used to cover a variety of phenomena. For example some economists have used it to describe a factor which cannot be varied during a given interval of time, e.g., [3, p. 304]; some economists have also noted that "... indivisibility is necessary for economies of size or scale" [3, p. 305]. This paper is concerned with indivisibility as a short-run phenomenon.

¹⁹ The "half-size tractor" to drive the "half-size tractor" [5, p. 132] apparently would not be a limit here. In any event I fail to see why, at some suitable price, the "half-size man" (in the technologically relevant sense) would not be forthcoming.

²⁰ The distinction between fixed and variable costs is also ambiguous. Whether a firm chooses to vary a particular cost depends upon the relative gains and losses of doing so. At some cost a contract can be broken (as any lawyer will gladly admit), a private radio network substituted for a telephone, and so on.

The only costs which legitimately (i.e., implied by economic theory) cannot be varied are "sunk" costs; such costs, of course, are irrelevant to the decision process.

²¹ The preceding statements are not inconsistent with an alternative meaning of indivisibility. As Alchian suggests, the term may be interpreted to cover the phenomenon whereby more durable "dies" result in more than proportional increases in output potential [1, p. 29]. In this sense indivisibility is simply the name given to the sign of certain partial derivatives; it does not explain anything.

The second issue is whether a firm would ever operate in the uneconomic region. The usual argument asserts that a competitive firm "... can never produce in the uneconomic region. For if the price falls below the lowest average variable cost (equals highest average return to the variable factor, given the factor price) it will incur negative quasi-rents"²² [3, p. 305, fn. 2]. A firm facing a negatively sloped demand, however, apparently may do so: "All that is required in order to encompass the uneconomic region ... is to regard some fixed amount of a factor ... as being indivisible during the period in question" [3, p. 304].

If the concept of indivisibility is rejected as a short-run crutch, must output programs within the uneconomic region also be rejected? Given the argument developed in Section II, the answer seems to be negative. As the firm considers alternative adjustment periods, the present value cost of varying one input may be sufficiently greater than the present value cost of varying the other input(s) that the firm may choose to operate in one of the uneconomic regions during some limited time period. If wealth, rather than profit, is used as the relevant criterion, a competitive as well as a monopolistic firm may choose to operate for a time in the uneconomic region—particularly if it is granted that uncertainty may exist regarding the permanence of the change in circumstances inducing the adjustment in output.²³

The preceding comments suggest that, for analytical purposes, it is necessary to show the uniquely determined iso-product curves in each uneconomic region.²⁴ Whether the firm will operate within any such region during a particular short run can only be determined *after* allowing for the appropriate cost and revenue considerations. Furthermore, although at most one such region would be relevant in the two-input case, $n-1$ regions may be relevant in the n -inputs case.

The concept of a priori fixed, indivisible inputs is misleading. Among other things, such an approach masks the implication that a competitive firm may find it profitable to operate for a time within the uneconomic region.²⁵

²² It should be noted that Borts and Mishan are working with a linearly homogeneous production function. Their statements would not be necessarily correct, even in the context of flow analysis, if, for example, the production function in question were homogeneous of degree less than one.

²³ R. H. Coase's suggestion that an input be considered "... as a right to perform certain (physical) actions" [4, pp. 43-44] is a promising point of departure for further investigations in this area.

²⁴ E.g., if the present-value cost of not using some resources is zero, the least cost path for these resources outside the relevant ridge lines would then be straight lines parallel to their respective axes.

²⁵ As Borts and Mishan point out, there is nothing necessarily uneconomic about operating in the uneconomic region.

IV

The traditional approach to the short run as a period in which some inputs cannot be varied is theoretically inadmissible. The substitution of a definition for the corresponding falsifiable hypothesis implied by economic theory masks some empirically relevant issues. In what proportion are inputs to be varied in the short run? Which inputs, if any, are to be held constant? Which regions of the production function are empirically relevant? Why?

The production function must specify which input-output combinations are technologically relevant; cost and revenue information alone can determine which combinations are economically relevant. If it is granted that variation in the input mix is not a free good, then the proportion in which inputs are varied in response to some change in market conditions will depend upon the relative costs and receipts of all the alternative production strategies technologically available to the firm. Moreover, traditional flow analysis yields propositions regarding behavior of the firm in the short run only at the cost of some ambiguities. The wealth-maximizing model suggests that, if "uneconomic" regions exist, they are relevant for competitive as well as for monopolistic firms.

FORECASTING ERRORS AND BUSINESS CYCLES

By JOHN A. CARLSON*

Evidence has accumulated showing that aggregated forecasts of sales by business men have had systematic errors [9, 10, 11, 14, 16, 18, 26, 27]. In periods of rising sales, business forecasts have tended to understate actual sales. In periods of falling sales, the forecasts have been too high. In other words, changes in sales have typically been underestimated.

Such empirical findings, however, are incompatible with the hypothesis of rational expectations recently developed by Mills [24, 25] and Muth [28]. The rational-expectations argument follows from the assumption that businessmen are maximizing creatures. When it costs a businessman something to make forecasting mistakes, he has reason to avoid them. Thus, if past forecasts have shown systematic errors that can be corrected in some mechanical way, the rational businessman will make the necessary adjustments, and any bias will disappear from his forecasts.¹

What are we to believe, the empirical results or the logic of the theorists? On the one hand, if the theory of rational expectations is relevant to real-world anticipations, then the reported data must have been distorted from what businessmen really expected.² On the other hand, if we accept as a fact the persistence of systematic errors, then businessmen have been either unwilling or else unable to correct for these errors.

We shall take the position in this paper that aggregated forecasts of sales should tend to underestimate changes, no matter how carefully individual forecasts have been prepared. Section I shows that this con-

* The author is associate professor of economics, Purdue University. He is grateful to Edward Ames, Rene Manes, and James Quirk for their helpful comments on an earlier draft of this paper but retains full responsibility for any shortcomings that remain.

¹ This argument has been disputed. Bossons and Modigliani [2, 3] claim that expected profit-maximizing decisions may be perfectly consistent with systematic forecasting errors; and as Theil has shown [32, sect. 3.3], an adjustment that removes bias from forecasts can increase the error variance. If these cases hold, the "rational" businessman may choose to leave his forecasts unadjusted.

² Underestimation of change as revealed by a regression of forecasted levels on actual levels can be reconciled with rational expectations [28]. This particular "regression bias," however, depends upon where one places the assumed error term that links actual and forecasted values. Furthermore, if rational expectations are assumed, there is no such bias to account for the findings that forecasted extrapolations of past changes are smaller than actual extrapolations [3]. Pashigian [31] finds, on the basis of a statistical test with OBE-SEC data, that he cannot reject the rational expectations hypothesis, but his results suggest that the type II error (accept when hypothesis is false) is greater than it would have been had he tested the hypothesis that changes in sales are underestimated by some moderate percentage.

clusion follows from generally accepted macroeconomic theory and from the hypothesis that sales expectations are adaptive. Section II surveys a few studies of sales expectations and finds that the theoretical formulations in Section I are fully compatible with available expectations data.

The argument about rational expectations may be relevant to simple microeconomic situations,³ but we reject the notion that feedback from aggregated individual decisions can be readily enough perceived by the individual decision makers for them to make appropriate adjustments in their forecasts. Section III reports an experiment with a classroom economy in which systematic forecasting errors continued for many periods despite the fact that the structure of the economy was relatively simple.

I. Changing Sales and Forecasting Errors: A Theoretical Link

The typical explanation of the theory of national income determination discusses why an economy should adjust toward its equilibrium level. Once the rationale for the "stability" of aggregative equilibrium has been presented, subsequent focus of theoretical attention is on positions of equilibrium. Theories of the impact of fiscal policy, monetary policy, or shifts of various assumed behavioral equations become exercises in comparative statics. The idea of disequilibrium fades from conscious thought.

In this section we intend to dwell on the possibility of disequilibrium as a useful concept in the theory of business cycles. In so doing we find that the phenomenon of systematic errors in forecasting sales is a direct implication of the theoretical formulation. Our belief that this is a useful way to view the business-cycle process is supported by empirical evidence examined in Section II.

Equilibrium

The essence of our argument can be seen most clearly with a very simple macroeconomic model. Net national product is determined by the output decisions of producers who anticipate selling the goods produced. Suppose capital goods are made to order. Planned net investment then equals the production of new plant and equipment (less capital consumption) plus planned additions to inventories. It follows that net national produce Y_t must equal expected sales by producers of consumer goods E_t plus planned net investment \bar{I}_t :

$$(1) \quad Y_t \equiv E_t + \bar{I}_t$$

³ The author has conducted market experiments in which the participants have had to make supply decisions in anticipation of the market price. In the experiments price adjusted to clear the market in accordance with a demand function not revealed to the participants. In these markets, very rapid convergence did occur even when the structure allowed for an explosive cobweb pattern [5].

It will also be useful later to express (1) in the form:

$$(1a) \quad Y_t - \bar{I}_t \equiv E_t$$

We shall postulate that actual consumption expenditures are a function of net national product and that the marginal propensity to consume is less than one. While any simple analytical function of Y_t is likely to depart from observed values of C_t , the introduction of a stochastic error term will not alter our basic conclusion. We shall therefore retain a deterministic function and assert:

$$(2) \quad C_t = C(Y_t) \text{ such that } dC_t/dY_t < 1$$

Equation (1) states that expected sales and investment plans determine Y_t . Equation (2) then indicates what the resulting level of actual sales will be. Nothing in these two equations guarantees that actual sales will be equal to expected sales. Suppose, however, that sales are forecasted correctly:

$$(3) \quad C_t = E_t$$

This assumption is equivalent to the familiar condition that saving must equal investment. To see this, we can substitute for E_t from (1a) and then manipulate (3) into the form:

$$(4) \quad Y_t - C_t = \bar{I}_t$$

The value of Y_t that satisfies equation (4) is frequently referred to as the "equilibrium" value of net national product and will be denoted by \bar{Y}_t . The value of \bar{Y}_t depends not only on the consumption function but also on \bar{I}_t . Since investment plans may change from period to period as may parameters of the consumption function, we shall refer to \bar{Y}_t as a "temporary equilibrium" to remind ourselves that the achievement of equilibrium does not guarantee that the same level of net national product will be maintained indefinitely [13, 30].

Disequilibrium and Forecasting Errors

A temporary equilibrium exists when actual consumption equals the level anticipated by businessmen. We now consider what happens when these two quantities are not equal. Suppose net national product Y_t is above the temporary equilibrium level \bar{Y}_t . From the assumption that the marginal propensity to consume dC_t/dY_t is less than one, it follows that:

$$C_t < Y_t - \bar{I}_t \quad \text{when} \quad Y_t > \bar{Y}_t$$

After substitution for $Y_t - \bar{I}_t$ from (1a) the preceding statement can be rewritten as:

$$(5) \quad C_t < E_t \quad \text{when} \quad Y_t > \bar{Y}_t$$

By a similar line of reasoning, we can state:

$$(6) \quad C_t > E_t \quad \text{when} \quad Y_t < \bar{Y}_t$$

Assumed Reactions to Disequilibrium

The remaining task is to relate statements (5) and (6) to the phenomenon of business cycles. Our contention is that the expansion phase of a business cycle is usefully viewed as a sequence of periods in which the economy is below a temporary equilibrium level.⁴

When sales have been underestimated in one period (and $Y_t < \bar{Y}_t$), we hypothesize that business forecasters will have higher expected sales in the next period. This hypothesis can be written:

$$(7) \quad E_{t+1} > E_t \quad \text{when} \quad C_t > E_t$$

Statement (7) is a form of adaptive-expectations hypothesis but without a parameter that specifies how much of an adjustment is to be made in expected sales when a forecasting error occurs [29].

When sales have been overestimated, we hypothesize that sales expectations will be adjusted downward. Symbolically:

$$(8) \quad E_{t+1} < E_t \quad \text{when} \quad C_t < E_t$$

We further assume:

$$(9) \quad Y_{t+1} > Y_t \quad \text{when} \quad Y_t < \bar{Y}_t$$

If $\bar{I}_{t+1} \geq \bar{I}_t$, statement (9) follows directly from (1) and (7). If planned investment drops, statement (9) assumes that such a drop does not offset the increased sales expectations.

On the basis of a similar argument we assume:

$$(10) \quad Y_{t+1} < Y_t \quad \text{when} \quad Y_t > \bar{Y}_t$$

The theoretical link should now be apparent. Statements (6) and (9) together imply that sales will be underestimated during expansions of business activity. During the early part of the expansion the temporary equilibrium itself may shift up with increasing planned investment. This, of course, helps to sustain the expansion.

When the economy eventually overshoots its temporary equilibrium the process will be reversed, unless there is some new stimulus to aggregate demand. By statement (5) sales will be overestimated. During the ensuing contraction there should be a sequence of periods in which net

⁴ The author is preparing a paper in which it is argued that this is the approach Hicks had vaguely in mind in his theory of trade cycle [17] but that he never successfully broke away from a dependence on his second-order difference equation, which was based on the assumption that aggregate supply always equals aggregate demand. It should be noted that the lag structure adopted here is in the Lundberg-Metzler tradition [22, 23].

national product falls and sales are consistently overestimated. This argument follows from (5) and (10).

An Example

To help clarify these points, imagine the following hypothetical situation:

Expected sales of consumer goods=2000

Planned additions to inventories=10

Planned net additions to capital=30

In this case production of consumer goods would be 2010, and net national product Y_t would be 2040.

Now suppose that the consumption function is:

$$(11) \quad C_t = 500 + .75Y_t$$

Given the planned net investment of 40, we substitute from (11) for consumption in equation (4) and find that the temporary equilibrium value \bar{Y}_t is 2160. We thus have actual Y_t of 2040 far below its temporary equilibrium. According to statement (6), actual sales should exceed expectations. From equation (11), actual consumption is $500 + .75(2040) = 2030$, which does lie above the expected sales of 2000.

Under these circumstances, what sort of reactions would we expect from the producers? By hypothesis, they will revise upward their sales expectations. Suppose they are conservative and anticipate sales to be about 2020 (a regressive forecast). If planned net investment in capital goods remains unchanged at 30 and if the planned additions to inventory goes up to 30 (in order to make up for the unexpected depletion in period t), then the production of consumer goods will rise to 2050, and net national product to 2080. With the assumed consumption function, sales will be 2060. This implies a forecasting error of 40; and the error would be even greater if investment in equipment were higher.

This underestimation of sales is attributable to the fact that production is below its temporary equilibrium level and not simply to the apparent conservatism of the forecasters. To see this, suppose that businessmen are much more optimistic and estimate that sales will soar to 2120. With a planned net investment of 60, consisting of 30 in inventories and 30 in capital goods, net national product would reach 2180 and the consumption function would call for sales of 2135, still in excess of the forecasted level. This example, of course, requires that goods are available and that capacity exists.

II. Relevant Real-World Data

Studies of sales anticipations have revealed several persistent attributes. Without cataloging all of the findings, we shall note three as-

pects of businessmen's sales forecasts that have relevance to the model under discussion here.

(1) Changes in sales are generally underestimated. This, of course, is the phenomenon for which an explanation has been offered. (2) Forecasters generally have an optimistic outlook, i.e., errors have been greater when sales are falling. (3) Forecasts have sometimes been regressive, i.e., businessmen do not invariably extrapolate changes in sales; they often appear to expect a reversal of the recent trend.

Change Understatement and Level Optimism

Ferber [9] [10] [11] and Hultgren [18] present details of the railroad shippers' forecasts. All three of the foregoing attributes emerge dramatically from these data. Modigliani and Sauerlender [26] find that the systematic errors (understatement of change) occur not only in the railroad shippers' data but also in surveys by Dun and Bradstreet, by *Fortune*, and by the Department of Commerce and the Securities and Exchange Commission.⁵ Of these, only the *Fortune* surveys lack a general upward bias to the level of forecasted sales. In other words, while changes in sales are underestimated, the errors are usually much greater when sales are falling than when they are rising. In this connection Ferber has postulated that business forecasters possess a "permanent optimism," i.e., a strong belief in an upward trend in sales.

One other quarterly survey of anticipations was begun in the second quarter of 1959 by the Office of Business Economics (OBE) in the Department of Commerce. The anticipations and corresponding actual sales (and inventories) of U.S. manufacturers of durable goods and non-durables are published quarterly in the *Survey of Current Business*. Foss [12] discusses the survey and provides some preliminary analysis of the data through the fourth quarter of 1961. Additional information is provided by Lovell [21].

An indication of the general optimism of sales forecasters is conveyed in an observation by Foss [12, p. 236]: every seasonally adjusted forecast of sales six months ahead is above the sales of the most recently completed quarter. We have carried the data through 1966 and this record is still unbroken.

The period from 1959 to 1966 can be divided into six quarters in which

⁵ Cooper and Simon [7] suggest that there must be either a statistical or psychological bias introduced into some of these survey results. Lovell [20] has proposed another possible source of error in the railroad shippers' forecasts. If the shippers do have an internal sales forecast, then errors in their derived carloading forecasts can result from the fact that not everything the shippers sell is shipped by rail. As support for this hypothesis, Lovell finds, in the cement industry for the period 1947-1956, that sales anticipations derived from reported carloading forecasts are more highly correlated with actual sales than are forecasted carloadings with actual carloadings [20, p. 218].

sales fell and 23 in which sales rose over the preceding quarter. Falling sales occurred in the last two quarters of 1959, presumably because of a steel strike and in the four quarters from early in 1960 to early in 1961. The average decline in sales over these six quarters was 1.57 billions of dollars per quarter. For the same six quarters the three-month forecasts indicated that the average expected decline was only .55 billions of dollars per quarter. Over the 23 quarters of rising sales the increase averaged 2.44 billions of dollars per quarter, and the average three-month forecast was for a rise of 2.10 per quarter. Thus, there is some indication that changes in sales are still being underestimated, although the errors are small compared with earlier data. In keeping with Ferber's "permanent optimism" hypothesis, the errors tend to be greater when sales are falling.

Regressiveness

Regressiveness has been analyzed in detail by Bossons and Modigliani [1] [2]. As they use the term, regressiveness refers in our notation to the following situation:

$$\begin{aligned} E_t < C_{t-1} & \text{ when } C_{t-1} > C_{t-4}, \text{ or} \\ E_t > C_{t-1} & \text{ when } C_{t-1} < C_{t-4} \end{aligned}$$

Since surveys are usually conducted quarterly, we shall say that a forecast for quarter t is regressive if the trend in sales over the last three quarters is expected to be reversed in the forthcoming quarter. The phenomenon of regressiveness is most evident in both the railroad shippers' forecasts and the Dun and Bradstreet data.

One reaction to these findings is reproduced here because the views expressed may foster a spurious objection to the expectations hypothesis presented in Section I of this paper. Hart and Kolin write [15, p. 261]:

Now if expectations are really regressive in this sense, we must infer that the whole course of a business upswing is a series of agreeable surprises, which keep things going up despite a tendency of business to reverse the upswing by decisions to cut back inventory, staffing, procurement, and the like. Admitting that it is hard to systematize the use of business-cycle evidence in this connection, we assert that our preference for nonregressive models is not sentimental. Rather, it reflects the large body of facts which lead most analysts of fluctuations to give much weight to "cumulative" elements in expansion and contraction, and to doubt the inherent stability of the business process. In the light of these facts, how can expectations simultaneously be regressive and be linked up with the decision processes which generate business fluctuations?

These remarks give the impression that we must choose between "regressive" tendencies and the view that business cycles are cumulative

processes. This is simply not true. The confusion arises because Hart and Kolin are comparing E_t with C_{t-1} instead of with E_{t-1} . If sales have been rising for a number of quarters and we find regressiveness, i.e., $E_t < C_{t-1}$, this need not imply $E_t < E_{t-1}$. As long as businessmen's expected sales rise over expected sales of the preceding quarter, an expansion can well continue despite regressive forecasts. The example in Section I included just such a case. Similarly there could be regressive expectations in every period of a decline and at the same time we might find $E_t < E_{t-1}$ throughout.⁶

A Test of Adaptive Sales Expectations

The hypothesis that sales expectations in the aggregate are adjusted adaptively is a key part of our theoretical link between forecasting errors and business cycles. In order to classify all possibilities, including cases in which forecasts happen to be correct or there is no change in the level of the forecast, we need to modify (7) and (8) slightly. Restated, our hypothesis takes the form:

$$(7') \quad E_{t+1} > E_t \quad \text{when} \quad C_t \geq E_t$$

$$(8') \quad E_{t+1} \leq E_t \quad \text{when} \quad C_t < E_t$$

Our choice of location of the weak inequalities is based on the hypothesis of "permanent optimism." If a forecast has been correct and the forecasters are generally optimistic, their sales expectations will be revised upward. By a similar line of reasoning, we assume that a forecast of no change in sales will follow an overestimate of sales rather than an underestimate. The negation of the hypothesis includes either of the following two cases:

$$(12) \quad E_{t+1} > E_t \quad \text{when} \quad C_t < E_t$$

$$(13) \quad E_{t+1} \leq E_t \quad \text{when} \quad C_t \geq E_t$$

Available data can now be put into cells of a 2×2 contingency table in order to test our expectations hypothesis. Table 1 contains a classified count of forecasts from the seasonally adjusted series that Hart [14] has

⁶ Nerlove [29, pp. 216-19] points out how regressive and adaptive expectations may be reconciled but he does not relate it to cumulative processes. In the appendix we show how Metzler's inventory models can incorporate adaptive expectations. Certainly, if the output of consumer goods is based on E_t in period t , it should have been based on E_{t-1} in period $t-1$. The relationship between investment in capital goods and expected sales of consumer goods is less clearcut. If the desired stock of capital goods is always proportional to expected sales and producers invest just enough to reach the desired stock, then planned investment depends directly on the difference $E_t - E_{t-1}$. This may be a naive formulation of the accelerator but it suggests that the size of E_t relative to E_{t-1} can influence investment decisions as well as decisions to change production. There is an evident need for more research into the link between stated expectations and actual decisions. A notable attempt is in the latter part of the paper by Modigliani and Sauerlender [26]. See also [4, 8, 19, 21].

Source: U.S. Dept. of Commerce, Office of Business Economics; and March, June, Sept., and Dec. issues of the *Survey of Current Business*. The forecasts for the fourth quarter of 1963 have been omitted because of a modification of the series at that point.

Table 2 contains a similar classification of more recent data. The seasonally adjusted sales forecasts of manufacturers of durable goods and nondurables have been considered separately. These data also tend to confirm our hypothesis. The pattern is again highly significant statis-

⁷ See *Tables for Testing Significance in a 2×2 Contingency Table*, compiled by D. J. Finney, *et al.*, Cambridge: University Press, 1963. These are tabulated on the basis of the hypergeometric distribution. Let the null hypothesis be that the probability of $E_{t+1} < E_t$ is independent of the relationship between E_t and C_t . With the railroad shipper's data, we note that of the 29 observations with $C_t < E_t$, 25 were followed by a lower forecast. According to the tables, at a .005 significance level, we can reject the null hypothesis if 9 or fewer of the 20 observations of $C_t \geq E_t$ were followed by $E_{t+1} < E_t$. In this sense 3 observations may be viewed as highly significant.

tically. Interestingly, the only adjustments contrary to the hypothesis occur because of the optimistic outlook of the forecasters. In none of these quarters were sales expectations lowered following an underestimate of actual sales.

III. *Experimental Evidence*

An advocate of the use of rational expectations in connection with sales forecasts, Mills [25, p. 34], has written:

In other words, if the economists' theory implies that a variable is generated by a particular process then he should not assume that expectations of the variable are formed in a way inconsistent with this process. This is particularly important if, as in the usual model, the variable is generated by a relatively simple mechanism that an intelligent decision maker, who is familiar with the series, can estimate.

A classroom economy developed and used by the author provides an interesting vehicle for examining Mills' contention.⁸ We shall present only a brief sketch here. For those interested, much greater detail is available elsewhere [6].

The basic plan of the classroom economy is to install students as managers of hypothetical firms producing an all-purpose consumer good, and ask them to make decisions for a sequence of periods. At the beginning of a period, a firm has a certain stock of capital equipment. The production function calls for fixed proportions of equipment and labor. Since the labor supply is assumed to be perfectly elastic, the production decision boils down to a judgment about how much of the firm's available productive capacity to utilize. At the beginning of a period, the managers must also decide how much new equipment to order for future use. Since equipment is assumed to deteriorate, the level of net investment in equipment can be negative as well as positive. There is also a rule that a firm's stock of equipment may not be expanded by more than a certain percentage in any one period.

In both experiments in which data on sales expectations were systematically collected, there were twenty firms. Two units of capital were required for each unit of output. Capital deteriorated at a rate of 2 per cent per period and could not be expanded at a rate of more than 4 per cent per period. Letting K_t stand for the stock of capital equipment at the beginning of period t , X_t for the production of consumer goods, and I_t for net investment in equipment, the two decision variables X_t and I_t were constrained as follows:

⁸ This course was taken by candidates for a Masters Degree in Industrial Administration at Purdue University during the Spring semester, 1965. One class was taught by William Breen and the other by the author. In each class there were 37 students and 20 firms. For each group of 20 firms, 17 had two managers and 3 had only one manager.

$$X_t \leq .5K_t$$

$$-.02K_t \leq I_t \leq .04K_t$$

The production and investment decisions create income, and income in turn generates demand for consumer goods. The consumption function, which was not revealed to the class except to the extent that it could be inferred from the national income accounts, took the following form:

$$C_t = 720 + 12t + .7(X_t + I_t)$$

where C_t denotes "potential sales." In any period C_t is a linear function of national income, but from one period to the next the function shifts upward.

Each firm shares equally in the market. If all firms have enough available for sale, actual consumption equals potential sales. If some firms have too little available, they lose sales that period. If a firm has more available than its share of the potential sales, then the unsold goods are carried over as inventories until the next period. Since prices do not change, this is a pure quantity-adjustment model.

The classroom economy also specifies a number of cost parameters. The most important to consider here are the cost of holding inventories and the cost of holding one unit of productive capacity for one period. The cost of capacity is determined by the depreciation and interest charges. The larger this capital cost is relative to the cost of holding a unit in inventory, the greater is the incentive to use capacity fully and temporarily build up inventories when demand falls below full-capacity production.

Two classroom economies designated Economy A and Economy B were given precisely the same instructions and had the same parameters, with the exception of the cost of holding inventories. In Economy A it paid to produce a marginal unit for inventory only if that unit could be sold within five periods. In Economy B, the critical interval was ten periods. Given the level of production, a change in expected sales must be matched by an opposite change in planned additions to inventory. If inventory costs are relatively inexpensive, then production may not be quickly adjusted to any revised sales estimates; but if managers are concerned about undesired inventory changes, production will be changed directly, if possible, with any change in expected sales, and the income effect of these decisions may vitiate the forecasts.

In the two classroom economies, a depression normally lasted three or four periods and expansions typically took from five to eight periods. It took about six or seven periods for a preceding peak in the level of production and investment to be surpassed. With these conditions, our theory suggests that the managers of firms in Economy A were bound

to make systematic underestimates of changes, since the rational policy was to be very much concerned about inventory buildup.

There was slightly more chance that the managers of firms in Economy B might forecast correctly and then not adjust production so as to thwart the sales forecasts. Since it was almost always rational to use capacity fully in this economy, a knowledge of capacity, a good guess as to net investment, and a fair approximation to the consumption function would enable a manager to make accurate forecasts. Beginning in period 10, firms submitted sales forecasts. When they made their production and investment decisions for a period, the managers were to record their forecasts of potential sales for the current period and for one additional period into the future.

One striking difference between the experimental data and sales forecasts by U.S. manufacturers is that the classroom forecasts are clearly extrapolative with some sensitivity to changes in the rate of change in sales and are adaptive only in the same sense that the sales expectations posited by Metzler [23] are often adaptive.⁹ An explanation is that in the classroom economy forecasters can be reasonably sure that, if their firm needs to increase or decrease production, most other firms do too. Sales can be extrapolated with confidence, since the managers have experienced the effect on sales from their own typical output decisions. In the real world there is much less certainty of any feedback on sales when a "typical" firm responds to a felt need to expand or contract its operations. It is also harder to tell in which direction the temporary equilibrium might be.

Despite their awareness of the interdependence between production and sales, the managers in the classroom economy rarely anticipated the full impact. The cases of underestimation of sales were almost always found during expansions, and overestimates generally occurred in contractions. To show the extent of this, we have prepared Table 3 in a manner similar to Tables 1 and 2. The difference is that we have related changes in Y , as posited by equations (9) and (10), to positions of disequilibrium ($C_t \neq E_t$).

The pattern for these experimentally generated data is, like the real-world data, in conformity with our hypothesis. In this case what contradictions there were occurred within a period or two of turning points. It is also interesting to note that most of the observations that do not

⁹ The relationship between adaptive expectations and the expectations function assumed by Metzler is examined in the appendix to this paper. The expectations data generated in the classroom economy are analyzed in [6]. The data in both economies had a remarkably close fit to approximately the following function:

$$E_{t+1} - C_t = 7 + .7\Delta C_t + .2\Delta^2 C_t$$

where $\Delta C_t = C_t - C_{t-1}$,
 $\Delta^2 C_t = \Delta C_t - \Delta C_{t-1}$

TABLE 3—TWO-WAY CLASSIFICATION OF FORECASTS GENERATED EXPERIMENTALLY IN TWO CLASSROOM ECONOMIES

| | Economy A | |
|---------------------------------|-----------------|--------------------|
| | $Y_{t+1} > Y_t$ | $Y_{t+1} \leq Y_t$ |
| Underestimate $C_t \geq E_t$ | 15 | 1 |
| Overestimate $C_t < E_t$ | 2 | 10 |
| | Economy B | |
| | $Y_{t+1} > Y_t$ | $Y_{t+1} \leq Y_t$ |
| Underestimate $C_t \geq E_t$ | 13 | 0 |
| Overestimate $C_t < E_t$ | 5 | 9 |

conform to our hypothesis are cases of increasing production after an overestimate of sales. The upward shift of the consumption function imparted growth into the system. The recognition of a growth trend in the classroom economy may have led the participants to prefer an error on the optimistic side, an experimental re-creation perhaps of Ferber's "permanent optimism." One thing these experimental results demonstrate is that some of the special difficulties encountered in actual surveys are not necessary for a systematic bias in the forecasts. There was no possibility of seasonality. There was a single product and no price changes. Hence, no ambiguity could arise from these sources.

Most of Mills' criteria for rationality in expectations were met by the classroom economy. The generating mechanism process was simple. There were no shifts in spending because of net foreign demand, government spending, or varying psychological propensities of consumers. The consumption function contained no stochastic component. The students were familiar with the series since national income data were reported after every period. They had plenty of time to think about the data since only one decision was made each time the class met, and there were a number of assigned problems asking them to analyze various aspects of the economy. The students were intelligent; and yet they had not settled on the long-run equilibrium path in almost forty periods.

In one sense we agree with Mills. Forecasts are not independent of experience. A decision maker who becomes aware of systematic errors in his forecasts is likely to make some adjustments in his forecasts if it is profitable to do so; but as long as the production decisions are related to

the forecasts and changes in sales are induced by changes in production and income, there is no guarantee that the forecasts will lose their bias.

There is some evidence that the managers in the classroom economies did change their forecasts. They became more attuned to changes in the rate of change in sales as an indication of turning points. In Economy A, in particular, the cycles were occurring with increasing frequency as managers were trying to avoid past mistakes. Perhaps these classroom economies would eventually have settled onto the equilibrium path, but this is by no means certain. If it proved so difficult to settle onto a steady growth path when there was a simple structure and relatively complete information, then it is not surprising, accepting our theory, that systematic forecasting errors occur in an economy whose structure is not easy to perceive and whose decision makers are frequently changing.

The proponents of rational expectations emphasize that forecasting errors will occur, but that the mathematical expected value for the errors ought to be zero and not be autocorrelated. A similar point should be underscored with regard to our claim about systematic forecasting errors. We generally expect the average forecast of a change in sales to be in error; but there is no reason why managers with sufficient information and insight cannot come up with unbiased forecasts. One firm in Economy A was managed by two students who did perceive what was going on more clearly and earlier than anyone else. Because of their understanding of the overall economic process, their firm was the runaway winner in terms of accumulated net worth. But if all managers had behaved as these two, the sales pattern would have been altered and a different set of decisions and predictions would have been more nearly optimal.

IV. *Conclusion*

The theoretical framework developed in this paper is consistent with a broad class of consumption functions and investment functions. A key expectations hypothesis has also been confirmed by available data. Thus, the oft-noted tendency of businessmen to underestimate changes in future sales does not require a statistical or psychological explanation. It is to be expected on the basis of economic theory.

APPENDIX: METZLER'S INVENTORY MODELS WITH ADAPTIVE EXPECTATIONS

In our description of the business cycle process we have stressed the nature of reactions to disequilibrium and have not tied ourselves to any rigid sequence or functional statement of the expectations hypothesis. We shall now assume a linear adaptive-expectations function and examine how it differs from the expectations function used by Metzler [23].

Let C_t denote actual sales and E_t expected sales. In parametric form a linear adaptive-expectations function can be written:

$$(A.1) \quad E_{t+1} = E_t + \rho(C_t - E_t) \quad 0 < \rho < 2$$

Metzler's expectations function has the form:

$$(A.2) \quad E_{t+1} = C_t + \eta(C_t - C_{t-1}) \quad -1 \leq \eta \leq 1$$

It is crucial to our description of business cycles as cumulative affairs that ρ be positive. The postulated upper limit of two is arbitrary.¹⁰ It corresponds roughly to Metzler's upper limit of one on η . When $\rho=1$ and $\eta=0$, the two hypotheses come to the same thing: naive expectations.

When $-1 \leq \eta < 0$, businessmen are predicting a reversal in the direction of the most recent change in sales. Let us denote such a forecast as *regressive*. When $0 < \eta \leq 1$, sales are expected to change again in the same direction as the most recent change. This sort of forecast may be called *extrapolative*.

Given the last forecast and the most recent change in sales, values of the coefficient of adaptive expectations ρ can be selected to yield either regressive or extrapolative forecasts. Suppose that $C_t > C_{t-1}$ and $C_t > E_t$ or that both inequalities are reversed. In those cases $0 < \rho < 1$ implies regressive forecasts and $1 < \rho$ implies extrapolative forecasts. Since our theory claims that $C_t > E_t$ during expansions and $C_t < E_t$ during contractions, the two functions can frequently be used to generate the same qualitative forecasts. It follows that the expectations assumed by Metzler are also adaptive much of the time.

At turning points, or whenever the cases specified above do not hold, the relationship is reversed. When $C_t > C_{t-1}$ and $C_t < E_t$ or when $C_t < C_{t-1}$ and $C_t > E_t$, $1 < \rho$ produces regressive forecasts, and extrapolative forecasts occur with $0 < \rho < 1$. Thus, not all forecasts of direction of change in sales generated under one hypothesis can be reproduced under the other if the coefficients of expectation are assumed to be constant over the cycle.

To show how the formal models differ we shall retain all of Metzler's assumptions and then substitute (A.1) for (A.2). Assuming the expectations function (A.2), Metzler has developed three different dynamic sequences corresponding to three different assumptions about inventory policy. We designate these below as cases 1, 2, and 3. They correspond to Metzler's third, fourth and sixth sequence, respectively.

Actual sales, or consumption, is assumed to be a linear function of current income Y_t :

$$(A.3) \quad C_t = A + bY_t \quad 0 < b < 1$$

The constant A in this function plays the same role as Metzler's autonomous investment v_0 .

¹⁰ In one sense these limits are not arbitrary. The function (A.1) can also be written as a series expansion:

$$E_{t+1} = \rho \sum_{n=0}^{\infty} (1-\rho)^n C_{t-n}.$$

Any wider limits than $0 < \rho < 2$ and this would not be a convergent series.

Y_t is generated by two components, production in anticipation of sales E_t and planned net investment in inventory I_t :

$$(A.4) \quad Y_t = E_t + I_t$$

Case 1: Passive Accumulation of Inventories

If businesses let inventories rise or fall depending on whether sales have been overestimated or underestimated and make no effort to offset these changes, then:

$$(A.5) \quad I_t = 0$$

Equations (A.2)–(A.5) correspond to Metzler's third model. By substitution they reduce to the following second-order difference equation:

$$(A.6) \quad Y_t - (1 + \eta)bY_{t-1} + \eta bY_{t-2} = A$$

As in all of the models considered in this appendix the equilibrium solution is $A/(1-b)$. The stability conditions for (A.6) require:

$$-(1 + b)/2b < \eta < 1/b$$

Since Metzler postulates $0 < b < 1$ and $-1 \leq \eta \leq 1$, instability is impossible.

Changing to adaptive expectations, the system of equations (A.1), (A.3)–(A.5) reduces to the following first-order difference equation:

$$(A.7) \quad Y_t - (1 - \rho + \rho b)Y_{t-1} = \rho A$$

The stability conditions can be expressed:

$$0 < \rho < \frac{2}{1 - b}$$

The two models have certain similarities. Both can give rise to a damped cobweb approach to equilibrium. In Metzler's model this may occur when forecasts are regressive ($\eta < 0$); for this to occur with (A.7) expectations must be strongly adaptive ($1/(1-b) < \rho$). Both have a portion of the parameter space in which there is a steady approach to equilibrium. The main difference is that (A.6) is a second-order difference equation. The characteristic equation can have complex roots and give rise to a cyclical pattern. This cannot occur with (A.7).

Case 2: A Desired Level of Inventories

Metzler has shown that if businesses try to maintain some fixed level of inventories, planned investment in inventories will always be equal to the difference between actual and expected sales in the prior period.

$$(A.8) \quad I_t = C_{t-1} - E_{t-1}$$

The four equations (A.2)–(A.4), (A.8) represent Metzler's fourth sequence. The resulting difference equation is:

$$(A.9) \quad Y_t - (2 + \eta)bY_{t-1} + (1 + 2\eta)bY_{t-2} - \eta bY_{t-3} = A$$

and the stability conditions are:

$$-\frac{1+3b}{4b} < \eta < \frac{1}{2b}$$

If we substitute adaptive expectations (A.1) for (A.2) in the foregoing model and manipulate the equations to obtain a function of Y , there is a new difference equation:¹¹

$$(A.10) \quad Y_t - (1 - \rho + b + \rho b)Y_{t-1} + bY_{t-2} = \rho A$$

with the stability conditions:

$$0 < \rho < \frac{2(1+b)}{1-b}$$

The characteristic equation of (A.10) has complex roots if

$$\frac{(1 - \sqrt{b})^2}{1 - b} < \rho < \frac{(1 + \sqrt{b})^2}{1 - b}$$

Therefore, cycles can arise with $b > 0$.

In Metzler's model unstable cycles occur if $b > .5$ and η is sufficiently large. The larger the value of b , the smaller the range of values of η that result in a damped approach to equilibrium. Just the opposite is true with adaptive expectations. The larger the value of b , the greater may ρ be without having instability. Actually, within the postulated ranges $0 < \rho < 2$ and $0 < b < 1$, instability cannot arise with adaptive expectations in this model.

Case 3: A Desired Ratio of Inventories to Sales

Suppose now that businesses seek to maintain a constant ratio of inventories to expected sales. In that case it is necessary to add to equation (A.8) the difference between the desired level of inventory in period t and the desired level in period $t-1$. Planned investment in inventories then becomes:

$$(A.11) \quad I_t = C_{t-1} - E_{t-1} + \alpha(E_t - E_{t-1})$$

Metzler's sixth and most complicated model consists of equations (A.2)-(A.4), (A.11). These reduce to the following third-order difference equation:

¹¹ Both (A.10) and (A.13) below can be obtained by substitution, but the appropriate trick is not readily apparent. A more straight-forward method is to rewrite the system of equations in matrix form by using the operator E , i.e., $EY_t = Y_{t+1}$, and solve by matrix inversion. For example, with this procedure one obtains:

$$Y_t = \frac{\rho A}{E^3 - (1 - \rho + b + \rho b)E + b}$$

which is equivalent to (A.10).

$$(A.12) \quad Y_t - [(1 + \eta)(1 + \alpha) + 1]bY_{t-1} + (1 + 2\eta)(1 + \alpha)bY_{t-2} - (1 + \alpha)\eta bY_{t-3} = A$$

In this model, stability requires

$$\alpha < \frac{3(1 - b)}{2b}$$

no matter what the coefficient of expectations. There is then the further restriction on the coefficient of expectations:

$$-\frac{1 + 3b + 2\alpha b}{4b(1 + \alpha)} < \eta < \frac{1 - (1 + \alpha)b}{(1 + \alpha)b[2 - (2 + \alpha)b]}$$

Both ends of this range approach -1 as α approaches $3(1 - b)/2b$.

The corresponding model with adaptive expectations contains equations (A.1), (A.3), (A.4), (A.11). By substitution, we obtain a second order difference equation:

$$(A.13) \quad Y_t - (1 + b - \rho + \rho b + \alpha \rho b)Y_{t-1} + (1 + \alpha \rho)bY_{t-2} = \rho A$$

with the stability conditions:

$$\begin{aligned} 0 < \rho < \frac{1 - b}{b\alpha} & \quad \text{for } \alpha > \frac{(1 - b)^2}{4b} \\ 0 < \rho < \frac{2(1 + b)}{1 - b - 2\alpha b} & \quad \text{for } \alpha < \frac{(1 - b)^2}{4b} \end{aligned}$$

Metzler observed that the introduction of a desired ratio of inventory to sales severely restricts the range of parameter values for which the system will tend to equilibrium. The same conclusion holds with adaptive expectations. Unlike Metzler's model, stability is still possible with large values of α and b , but this restricts ρ to an implausibly small range. The destabilizing potential of this inventory policy is not appreciably mitigated by adaptive expectations.

THE DEMAND FOR HIGHER EDUCATION IN THE UNITED STATES, 1919-1964

By ROBERT CAMPBELL AND BARRY N. SIEGEL*

This is a study of the demand for higher education in the United States for the period since World War I. The study is based upon aggregate enrollment data and it uses the rather common economic variables of income and price (tuition) to explain the movements of demand during the period. To anticipate our conclusions, we have found that these two variables explain some 87 per cent of the variation of demand for higher education as we have measured it. In addition, we have found that demand responds positively to changes in income and negatively to changes in price. We believe that these results have important implications for the theory of educational demand and for the conduct of national educational policy.

I. Theoretical Basis of Demand Estimates

Our results make sense only if we can put them in touch with a reasonable theory of educational demand. There are two not necessarily mutually exclusive approaches to such a theory. One approach views the decision to enroll in an institution of higher education as an investment decision, while the other views it as a current consumption decision. Both of these approaches can be integrated for the purposes of this paper.

The investment approach¹ to the theory of educational demand asserts that an individual will purchase a college education if the present value of the expected stream of benefits resulting from the education exceeds the present cost of the education. The expected stream of benefits includes two elements: the additional lifetime money income resulting from higher education and the additional social and intellectual amenities which a person might expect to receive as a result of having gone to college. The first benefit makes a college education similar to a producer durable, while the second causes it to resemble a consumer durable, whose yield is real rather than monetary.

The cost of a college education must also be viewed rather broadly. It includes direct money outlays in the form of tuition and fees, books,

* Both authors are professors of economics at the University of Oregon. They wish to acknowledge the support provided by the Center for the Advanced Study of Educational Administration, University of Oregon. Mr. Lee Feldman, graduate assistant with the Center was very helpful at every stage of the research.

¹ Now widely adopted. See in particular T. W. Schultz [7] and Gary Becker [1]. A useful defense of the approach is given by Mark Blaug [2].

differential living costs, and other outlays incident to going to school. An enrollment also entails indirect financial burdens in the form of opportunity costs, as measured by the loss of income incurred while in school. Finally, there are nonmonetary costs which include such things as the burden of study and, for some students, the pain of being away from home.

As with other investments, purchase of an education entails risks. The expected stream of benefits may fail to materialize, either because the student may fail to complete his education or because expected post-educational opportunities may not materialize.

An individual facing an enrollment decision presumably makes his decision in the light of the expected benefits and costs involved in an enrollment. For any given set of benefits and costs there will be an implied rate of return on the educational investment. The rate of return will be composed of two parts, one relating to the stream of monetary benefits and costs and another relating to the nonmonetary benefits and costs. Conceptually, these two elements are incommensurate; hence, we must imagine that the individual places some sort of monetary valuation upon the real part of the stream of benefits and costs. Whether or not individuals actually do this is, of course, an open question. Indeed, it is difficult to imagine how, in principle, such valuations can be made. The value to the individual of the stream of expected real benefits should equal the minimum compensation the individual would accept in order to induce him to give up those benefits but still undertake his education. In a similar vein, the real costs of an education may be valued by the maximum amount of money a person would pay to avoid them, while still expecting to receive the future stream of benefits. Such a procedure implies that real benefits can be sold and that relief from real costs can be bought. It is hard to see how this can be done. Fortunately, it is not our purpose here to measure the expected rate of return on an educational investment. Nevertheless, since such a concept is crucial to the investment approach, we shall assume that individuals act according to estimates of such a rate of return, with due allowance for the riskiness of their investments.²

Ordinary investment theory would have the individual compare his expected rate of return with some appropriate interest rate. An education will be purchased if the expected rate of return exceeds the rate of interest. The education will not be purchased if the interest rate exceeds the rate of return. An aggregate demand schedule for enrollments may then be derived by arraying individuals according to their expected rates of return (from highest to lowest). The total number of enrollments

² Mark Blaug also argues for such an assumption [3]. This article appeared after we had completed this paper.

demand will equal the aggregate of all enrollments for which the rate of return exceeds the rate of interest. Variations in the rate of interest will lead to inverse variations in the number of enrollments demanded.

This theory of enrollment demand depends heavily upon the assumption that loan capital will be available to all those who wish to purchase an investment. Although the situation is changing rapidly, this assumption is a bad one. The supply of credit for educational lending is still highly imperfect, and most individuals must depend upon personal or family resources, personal loans, or gifts and scholarships. For this reason, we should expect the actual demand schedule for enrollments to be below the schedule described above, since there will be many profitable educational investments which cannot be made for lack of finance. We should also expect aggregate demand to be relatively insensitive to changes in market rates of interest.

Variations in enrollment demand are related to variations in the factors affecting the expected rate of return. A general rise in expected money income, or a reduction in the uncertainty of acquiring the income, from educational investments, should increase the demand for higher education. An increase in the cost of educational investments, either in the form of an increase in opportunity costs or in the form of increased direct money outlays, should lead to a reduction in educational demand. Finally, because people must substitute personal for borrowed resources, we may expect the demand for higher education to vary directly with disposable family or household income.

Turning to the consumption approach to educational demand, we have already argued that a college education can be considered as a consumer durable, yielding a stream of future services over the lifetime of the individual. It is also true that an enrollment may bring current consumption benefits. These benefits include the many social, intellectual, and athletic activities available in most colleges and universities in the United States. We cannot directly measure the value of these benefits, but we may suppose that it is in some approximate sense measured by the outlays an individual would have to make to buy a substitute bundle of goods and activities outside of college. This method of valuation implies that the cost of current consumption benefits varies directly with the prices of consumer goods in general.

The consumption approach supplements and enriches the investment theory of educational demand in several ways. First, it allows us to offset part of the current costs of enrollment with a positive current benefit. Second, it allows us to strengthen the predicted effect of income upon the demand for enrollments. If both future and present consumption benefits from education are normal goods, an increase in income should lead directly to an increase in enrollment demand. This income effect is

quite separate from the earlier effect mentioned in connection with the lack of loan capital.

Finally, the consumption approach allows us to argue that educational demand is sensitive to the money costs of an enrollment relative to current consumer goods prices. For, consider a rise in the price level of all consumer goods relative to current tuition charges and other enrollment costs. Such a rise implies a reduction in the cost of the future consumption benefits from an education relative to the cost of present consumption goods in general. Conventional demand theory suggests that such a reduction will lead to the substitution of future consumption (through increased enrollments) for present consumption. An additional effect, working in the same direction, arises from the fact that the current consumption benefits from enrollments are valued by their substitutes among other consumer goods. The increase in consumer goods' prices raises the value of the current consumption benefit from enrollments. Since the value of the current consumption benefit offsets the money and real costs of an enrollment, the net cost of enrollments should fall. This, in turn, works to raise the expected rate of return from education and, hence, to increase enrollment demand.

In summary, our theory argues that, for a given population, enrollment demand should vary positively with expected money and real yields from education, positively with income, positively with the consumer price index, and negatively with the money and real costs of education. We now proceed to the empirical specification of the demand model.

II. *Measurement of Demand*

Enrollment data provide the most obvious source of information on demand. It is customary to express enrollment as a ratio of some relevant population group in order to measure the intensity or pervasiveness of demand for higher education within the relevant group. The U.S. Office of Education, for example, publishes widely used ratios of enrollments of various types (undergraduate, graduate, etc.) to both the 18-21 and the 18-24 year old age groups [8, p. 76]. While such ratios may be useful for some purposes, they are not useful for ours. We need a measure which relates enrollments to those in a position to choose to go on to college at any particular point in time. People lacking a high school diploma or its equivalent, for example, are rarely in a position to enter an institution of higher education of any sort. Neither is it possible for people who are institutionalized, immobilized for reasons of health, or who are members of the armed forces to go to college, even if they possess high school diplomas. It is for these reasons that we have chosen to measure demand with the ratio of undergraduate enrollment to those in

CHART 1. UNDERGRADUATE ENROLLMENT IN FOUR YEAR INSTITUTIONS, ELIGIBLE COLLEGE AGE POPULATION, AND TOTAL POPULATION AGED 18-24 1919-1964 (WORLD WAR II YEARS EXCLUDED)

Sources: See Appendix.

the 18-24 year age group who possess high school diplomas and who are not in the armed forces. We shall call this group the *eligible college age population*³ or, for short, the "eligibles."

Chart 1 plots the movements of enrollments, eligibles, and the 18-24 year population on a semilogarithmic scale for the years 1919 to 1964. For reasons which will be explained below, we have chosen to use resident

³ We use the 18 to 24-year old age group because it seems to contain about 80 per cent of the undergraduate population. See A. Cartter and R. Farrel [4, p. 120]. We were not able to obtain data by age of the institutionalized population. For our methods of estimating the "eligibles," see the appendix at the end of the paper.

undergraduate degree enrollment in four-year institutions as our measure of demand. Movements of the enrollment ratio as we would measure it can be inferred from the vertical distance between the top two series. The ratio published by the Office of Education is measured by the vertical distance between the top and the bottom series. The chart shows that the ratio of enrollment to the total 18-24 year group has risen continuously and extensively since 1919, whereas the ratio of enrollment to the eligible college age population has had no trend during the same period.⁴ The rise in the Office of Education ratio is evidently due to the increase over the period in the proportion of people in the 18-24 year group who have completed a high school education. We do not know if this long run increase in demand for high school diplomas is derived from the demand for higher education, or from a combination of factors including the demand for higher education. We do believe, however, that the demand for high school diplomas is sufficiently complex to warrant a separate study. Here we confine ourselves to the problem of the demand for higher education among those who are in a position to make a choice for or against going to college, i.e., among those we have defined as the eligible college age population.

Although there was no trend in the ratio of undergraduate enrollment to the eligible group during the 1919-64 period, Chart 1 does reveal that the ratio fluctuated during the period. It began to fall in the late 1920's and remained depressed during the 1930's. After World War II the ratio increased and fluctuated around its level for the 1920's. While the absence of trend in the ratio suggests that there has been no basic change in the taste for higher education among those in a position to choose to go to college, the fluctuations in the ratio strongly suggest the existence of a relationship between the demand for higher education and the economic variables discussed above.

III. *Formulation of the Empirical Demand Model*

Ideally, a statistical test of the theory of enrollment demand would require data on both educational costs and finance as well as expected differential income streams for those eligible to enroll. We do not have all the necessary data, even to an approximation, in the form of continuous time series. We do have, however, some data which can be related to elements in the earlier described model.

The financial costs of investing in college enrollment can be represented by an index of tuitions, deflated by the consumer price index.⁵

⁴ B. A. Jaffe and Walter Adams [5] have found that there has been no trend for a full century in the proportion of people going on to college after high school. Their findings are based upon backward projections from 1940 and 1960 census data on educational levels achieved by various age groups, a method quite distinct from ours.

⁵ It is assumed that other financial costs will tend to vary directly with the consumer price index.

Since this is equivalent to introducing the familiar relative price variable of demand analysis, it should also help to explain the demand for enrollments as present and future consumer goods. Similarly, consideration of both the producer and consumer good aspects of an enrollment requires data on both the amounts and sources of funds used to purchase enrollments. Since we have limited information on such matters for the period of time of the study, we have chosen to use estimates of real disposable income per household. We assume that other financial resources vary with this measure.⁶

The model also calls for some measure of opportunity costs. We have not included such a variable primarily because it is difficult to find a satisfactory measure. Income from jobs available to high school graduates provides, to be sure, a measure of opportunity costs. To some extent, this measure is already included in our household income variable. Nevertheless, it is still not clear that the availability of such jobs works consistently in the direction of reducing enrollment demand. Students who work draw their incomes from jobs very similar to those available to young high school graduates who do not enroll in college. Hence, an increase in such opportunities may well work to increase, as well as to decrease demand. Because of this ambiguity, we have decided to exclude opportunity costs from the test of the model.

A formal statement of the model is given by equation (1):

$$(1) \quad N_t = f_1(Y_{Ht}, P_t, E_t),$$

where N_t is undergraduate degree enrollment in 4-year institutions in year t , Y_{Ht} is real disposable income per household in year t , P_t is average real tuition in year t , and E_t is the number of 18–24 year old eligibles in year t .

For equation (1) to provide a test of our demand model, certain conditions must be satisfied. The most important is that enrollments not be constrained by institutional restrictions—e.g., entrance requirements beyond the minimum requirement of a high school diploma. Since N_t is the aggregate of undergraduate enrollments in 4-year institutions, we believe that we can assume such constraints away. In the United States, there is probably an institution of higher education for virtually anyone who both possesses a high school diploma and has the necessary financial resources.⁷

⁶ Note, we have not adjusted our income concept for size of family or size of household. While it is true that larger families with given incomes will have more difficulty in sending their children to college, we believe that much of this difficulty is resolved by sending children to less costly schools and by throwing a larger burden of finance upon the student himself. Studies of aggregate enrollment demand are therefore not likely to pick up a large effect from variations in family size. On the dubious statistical relationship between family size and family support for students, see John Lansing, Thomas Lorimer, and Chikashi Moriguchi [6, p. 32].

⁷ See M. Blaug [3, pp. 171–72] for a similar opinion.

In addition we assume: (a) that the enrollment demand function is homogeneous, and (b) that eligibles over the period of the test have not, on the average, changed their tastes for higher education.

Since we wish to study the *ratio* of enrollments to eligibles, we can convert equation (1) into the general form

$$(2) \quad \frac{N_t}{E_t} = R_t = f_1(Y_{Ht}, P_t).$$

Note that equation (2) requires f_1 to be homogeneous of degree one in E_t , i.e., that changes in E_t do not carry with them compositional changes in the population of eligibles which might affect R_t . Among such changes, for example, would be relative increases in eligible individuals who have strong preferences for higher education. We believe that our statistical results support this assumption and turn now to the estimation of the demand function.

IV. *Estimation of the Demand Function*

Chart 2 presents on a logarithmic scale the raw materials for our test: (1) the ratio of undergraduate enrollment in 4-year institutions to eligible 18–24 year olds; (2) real disposable income per household; and (3) an index of tuition costs deflated by the consumers' price index. Note that only nine observations for the period 1927–1963 appear in the Chart. While we have more complete data on the enrollment ratio and real disposable income per household, ready estimates of tuition costs are available only for the nine years indicated.⁸

Inspection of Chart 2 appears to support our hypotheses about the behavior of the demand for education. The enrollment ratio tends to vary directly with variations in real household income and inversely with the index of relative tuition costs. In the 1950's and 1960's the enrollment ratio approximated its value in the 1920's. Without our hypothesis concerning the importance of price, this would be puzzling behavior. Real household income was much higher in the 1950's and 1960's than it was during the 1920's, and one would have expected higher income to have a positive effect on the ratio. We believe that the absence of an upward trend in the enrollment ratio during 1919–64 was due to the negative influence of price offsetting the positive influence of income on the demand for higher education.

Although only nine observations⁹ were usable for regression analysis, we feel these years to be sufficiently representative of the period as a whole to justify such an analysis. Our regression took the form:

⁸ See the appendix for the sources and procedures used in the various estimates.

⁹ The years were 1927, 1931, 1935, 1939, 1947, 1951, 1955, 1959, and 1963.

CHART 2. RATIO (R) OF UNDERGRADUATE ENROLLMENT IN FOUR-YEAR INSTITUTIONS TO ELIGIBLE COLLEGE AGE POPULATION, INDEX (P) OF TUITION COST, AND REAL PERSONAL DISPOSABLE INCOME PER HOUSEHOLD (Y_h) FOR SELECTED YEARS 1919-1964

Sources: See Appendix.

$$(3) \quad R_t = b Y_{Ht}^\alpha P_t^\beta \text{ or taking logarithms,}$$

$$(3a) \quad \log R_t = \log b + \alpha \log Y_{Ht} + \beta \log P_t$$

The regression tests our hypotheses (1) that the income effect upon R_t is positive (that $\alpha > 0$) and (2) that the price effect is negative (that $\beta < 0$). The results are consistent with these hypotheses (standard errors are in parentheses):

$$(3b) \quad \log R_t = .7425 + 1.2036 \log Y_{Ht} - .4404 \log P_t$$

(.3702)* (.1942)** (.1506)***

Coefficient of Multiple Correlation = .9316

$$F = 19.701$$

$$F_{.01} = 10.92$$

* Not significant, using $t_{.05}$ in a two-tailed test.

** Significantly greater than zero, using $t_{.005}$ in a one-tailed test.

*** Significantly less than zero, using $t_{.025}$ ($= 2.447$) in a one-tailed test.

Unfortunately, our results do not permit a verification of our belief that R_t was trendless during the 1919–64 period because of the offsetting effects of income and price. Although α and β possess the necessary signs, the rather large standard errors associated with their estimated values rules out a precise prediction of R_t . At the same time, while we have not verified our hypothesis, we certainly have not rejected it.

V. *Two-Year College Enrollments*

The estimated demand function—equation (3b)—relates the ratio of undergraduate enrollment in 4-year institutions to the eligibles in the 18–24 year old age group. The calculations exclude both graduate students and students enrolled in 2-year institutions. It is perfectly legitimate to exclude graduate students, since both the age levels and eligibility requirements for graduate work differ sharply from the age levels and eligibility requirements for undergraduate work.

The exclusion of enrollments in 2-year institutions, however, does not have equal legitimacy. To be sure, a high school diploma is not necessary for matriculation in many of these institutions and vocational training, not ordinary college work, is the objective of many students in these institutions. Nevertheless, we are uncomfortable with the exclusion of enrollments in 2-year institutions, since an enrollment in a 2-year institution can be a substitute for an enrollment in the freshman and sophomore level in a 4-year institution.

Since there is no firm basis for separating students who seek vocational training from those who use a 2-year institution as a substitute for a 4-year school,¹⁰ these students can be treated in only two ways: (a) we can exclude them from the enrollment ratio, as we have done, or (b) we can include them in the ratio and seek an interpretation of the change in the ratio.

If enrollments in 2-year institutions are included in the numerator of the enrollment ratio, a definite upward trend appears. As Table I indicates, most of the trend appears after World War II, a period during which the number of junior colleges and community colleges expanded rapidly.

If we choose to regard the bulk of enrollments in 2-year institutions as substitutes for enrollments in the first two years of 4-year institutions, the theory outlined above can easily explain the resulting upward trend in the enrollment ratio. Two-year colleges are usually low cost institutions—in terms of living costs, tuition, and fees—relative to most competing 4-year institutions. In addition, their closeness to students' homes and their flexible programs make it relatively easier for students

¹⁰ The *Digest of Educational Statistics* [8] contains a breakdown for recent years, but not for earlier ones.

TABLE 1—ENROLLMENT RATIOS FOR UNDERGRADUATES, SELECTED YEARS 1919-64

| Year | 2- and 4-Year Institutions (1) | 4-Year Institutions Only (3) | Difference Between (1) and (2) |
|------|--------------------------------------|------------------------------------|-----------------------------------|
| 1919 | .328 | .323 | .005 |
| 1927 | .320 | .305 | .015 |
| 1931 | .246 | .225 | .021 |
| 1939 | .201 | .179 | .022 |
| 1947 | .332 | .299 | .033 |
| 1951 | .309 | .276 | .033 |
| 1952 | .321 | .277 | .044 |
| 1953 | .339 | .290 | .049 |
| 1954 | .348 | .299 | .049 |
| 1955 | .356 | .305 | .051 |
| 1956 | .377 | .323 | .054 |
| 1957 | .382 | .326 | .056 |
| 1958 | .382 | .326 | .056 |
| 1959 | .371 | .316 | .055 |
| 1960 | .368 | .311 | .057 |
| 1961 | .372 | .310 | .062 |
| 1962 | .384 | .317 | .067 |
| 1963 | .393 | .326 | .067 |
| 1964 | .395 | .326 | .069 |

Sources: See Appendix.

to acquire part-time employment. Finally, the presence of many low quality students in these institutions reduces competition for able students. The combination of easier financial burdens plus less intensive competition reduces the risk of not completing schooling anticipated by many students in the first 2 years of college. Lower costs, easier work opportunities, and reduced risk all work in the direction of increasing the demand for higher education.

VI. Conclusion

Our empirical results are easily summarized in two propositions: (1) Since 1919 there has been no trend in the ratio of enrollments in 4-year institutions to the eligible population; and (2) the fluctuations in the ratio which have taken place are associated with fluctuations in disposable income per family and an index of tuition as deflated by the consumer price index. The income and price elasticities of demand (using the enrollment ratio as a measure of demand) are $+1.20$ and $-.44$. Although both of these elasticities were statistically significant when tested against the null hypothesis, we are well aware that our small sample of observations has prevented us from making reliable estimates of the elasticity coefficients. It follows that the results of the study are less useful for forecasting purposes than they might have been with a larger sample. We do believe, however, that the results substantiate, at

least in part, the model of educational demand we postulated in the paper. Unfortunately, however, the model we used was a hybrid investment-consumption model, and our results cannot be used to separate out the contribution of each of these elements to the demand for higher education. Such a separation is, in our minds, a useful area for further research.

APPENDIX: SOURCES AND METHODS OF STATISTICAL ESTIMATES

1. *Eligible College Age Population*. With certain exclusions, this group was estimated from 7-year cumulative totals of high school graduates, beginning with the seventh year prior to the year for which the estimate was required. *Historical Statistics of the United States, Colonial Times to 1957* (1960) and the *Statistical Abstract of the United States* (both published by the U.S. Department of Commerce) provided data for most of the years. Since graduation data appeared biannually for most of these years, it was necessary to interpolate for the missing years. The elements of the cumulative totals were adjusted for death rates. Armed service high school graduates in the 18-24 age group were estimated for 1940 to 1964 by taking the ratio of the 7-year cumulative total to the total 18-24 year age group and multiplying the result by the number of 18-24 year servicemen (calculated from the *Current Population Report*, P-25, #98, U.S. Bureau of the Census). Since age breakdowns of servicemen prior to 1940 are not available, the ratio was multiplied by the total number of enlisted men for these years, on the assumption that this group comprised the bulk of servicemen in the appropriate age group. Official data on the age and educational composition of the armed forces are extremely sketchy, especially for earlier years. Nevertheless, perusal of *Selected Manpower Statistics* (Directorate for Statistical Services, Office of the Secretary of Defense, 19 February, 1965) will show that our assumptions are warranted for the years since 1948. As noted in the

text, we did not have estimates of the institutionalized population in the appropriate age group. More important, we did not exclude people in the 18–24 age group who had already received college degrees. We do not think that the year-to-year variation in the enrollment ratio will be much affected by the inclusion of this group. In any event, we had no hard data on the age distribution over time of college graduates.

2. *Enrollment Data.* *Historical Statistics* and the *Digest of Educational Statistics* [8] provided the basic sources for our estimates. It was necessary to splice together earlier and later enrollment estimates in order to put them on a comparable basis. Those presented in *Historical Statistics* for 1919–53 were based upon cumulative estimates for the academic year. Those presented in the *Digest* were for Fall enrollments, 1939, and 1946–64. The Fall enrollment figures were “blown up” by a factor relating the Fall and cumulative enrollments in four common years. In addition, in order to derive undergraduate enrollments it was necessary to estimate graduate student enrollments for a number of years.

The quality of the pre-World War II enrollment figures has long been suspect by students of higher education. Jaffe and Adams [5], for example, chose to work with backward projections of census data rather than enrollment data for this reason. We did not do so because such a method would not have yielded enough years to be useful in estimating the demand function. In any event, it is striking that our method comes to much the same conclusion about trends in the enrollment ratio that Jaffe and Adams came to. Our confidence in the usability of the official enrollment data has been increased by the Jaffe-Adams study.

3. *Tuition.* *The Fact Book on Higher Education* (Washington: American Council on Education) publishes various indexes on tuition and other student costs in looseleaf form. We constructed an index weighted by the number of students enrolled in public and private institutions and based upon the indexes of tuition and fees presented on page 263 (dated March 1964) of the *Fact Book* for 99 private and 33 public institutions. As noted in the text, only 9 years of estimates are available from this source for the period of the study.

4. *Disposable Income per Household.* Based upon data in *Historical Statistics*, *Statistical Abstract*, and the *Annual Report of the President's Council of Economic Advisers*, 1965 (Washington, 1965). We would have preferred to use estimated income per family, especially in those families where the head is 35–55 years of age and income exceeded a specified minimum. Such detailed income distribution data is not available for the pre-War period, except for 1929 and 1935–1936.

INCOME DISTRIBUTION AND PLANNING FOR PUBLIC INVESTMENT

*By A. MYRICK FREEMAN III**

The purpose of this paper is to examine the implications of introducing income redistribution as a policy goal in public investment planning and project selection. The model was initially developed to apply to water projects, but it can be generalized to apply to any federal investment where benefits and costs are tangible and beneficiaries do not bear the full costs of the project.¹

The basic criterion for evaluating public investment is the change in social welfare which results. The benefit-cost criterion which is normally used is based on the assumption that the change in national income is a good measure of the change in social welfare. When projects are designed to maximize net benefits and when all projects with positive net benefits are undertaken, the increase in national income will be at a maximum. But the benefit-cost criterion is sufficient to achieve maximum social welfare only if one of two conditions is met. Either equal increments to income must have the same welfare significance no matter to whom they accrue (the distribution of income does not matter); or there must exist a separate tax and transfer system or some other means for achieving the desired or "proper" distribution of income.

The basic assumptions of this paper are that income distribution does matter, and that there is not and will not be a completely effective tax and transfer system capable of achieving the desired distribution of income. I assume that there is a widely held value judgment which

* The author is assistant professor of economics at Bowdoin College. This paper is a revised section from an unpublished doctoral dissertation submitted by the author to the University of Washington. The author wishes to acknowledge the helpful comments of Professors Walter Y. Oi and William D. Shipman in detecting errors and omissions, and those of Professor Paul G. Darling that were made on an earlier draft of this paper. The research on which the dissertation was based was supported by a fellowship from Resources for the Future, Inc. Errors and opinions are the sole responsibility of the author.

¹ If beneficiaries bear full cost, there is no subsidy and no redistribution problem of any consequence. The list of federal programs which do involve subsidies and redistribution effects is long. It includes urban renewal, the several agricultural income and price support systems, and the various manpower, labor retraining, and educational programs. If the kind of analysis that is outlined below is applied to these programs, it seems likely that some may be found to have "undesirable" distribution effects, while others which might not pass the benefit-cost test might be shown to have positive redistribution effects which outweigh the efficiency cost. At the very least any attempt to apply this model to one of these programs would produce information about the distribution of benefits and costs which would be very interesting in its own right. For earlier efforts to evaluate the distribution effects of public investment in water resources see [4], [2], and [3]. The latter two utilize explicit welfare criteria.

enables us to say that society prefers a more equal distribution of income, *ceteris paribus*, over a less equal distribution, at least for small changes from the present distribution. I also assume that there are barriers to the increased utilization of the tax and transfer system. It does not matter whether these barriers are taken to be increasing dead-weight or administrative costs or some form of ethical or political aversion to "confiscation" and "give-aways."

Granted these assumptions, maximizing the net benefits of federal investments, as normally defined, does not necessarily yield the maximum increment to social welfare. Of two projects with the same net benefits, the one which through its distribution of benefits and costs moves farther toward the desired distribution of income will be preferred. Not only will selection of existing alternative projects be influenced by redistribution considerations, but also the design of a project might be different if its purpose is to maximize social welfare rather than national income. In the following sections the nature of the design problem will be illustrated, a social welfare function will be assumed, and a project design and selection criterion will be derived.

I

The nature of the problems that arise when income distribution effects must be considered can best be seen by studying a model project. Assume a proposed project to construct facilities to produce and deliver an intermediate good, X . The scale of the project can be measured in units of its annual supply of X which is assumed to be a uniform stream known with certainty over the life of the project. The cost of the project is:

$$(1) \quad C = C(X).$$

The units of measurement in this and subsequent equations are annual equivalents of the actual streams of costs, etc., calculated by using the appropriate discount rate.

Let X be the only variable factor in the production of Q :

$$(2) \quad Q = Q(X, F),$$

where F is the fixed factor. If P_q is the competitive price of the final product, Q_x is the marginal physical product of X , and VMP_x is the value of marginal product of X , then:

$$(3) \quad VMP_x \equiv P_q Q_x.$$

Since there is only one variable factor of production, VMP_x defines the demand curve for X . The demand curve can also be expressed in the inverse form. If P_x is the price of X ,

$$(4) \quad P_x = P_x(X).$$

In conventional benefit-cost analysis the benefit of the project is taken to be the maximum aggregate willingness to pay for X on the part of the producers of Q . Assume that the producers are profit maximizers. The benefit is given by:²

$$(5) \quad B = \int_0^X P_x(X) dX = \int_0^X P_q Q_x dX.$$

The increment to national income, or the net benefit, is:

$$(6) \quad N = B - C.$$

This is maximized when:

$$(7) \quad P_x = VMP_x = MC_x \quad \text{and} \quad B(X) - C(X) \geq 0$$

where MC_x is the marginal cost of producing X . Strictly speaking only the equality of marginal cost and value of marginal product need hold in the first equation. This equality defines an efficiency maximizing or optimum scale of project, X^* , and provided this scale of project is chosen, the output could be supplied at any price less than VMP_x . The only problem would be one of rationing the optimum quantity among users whose demands would sum to more than X^* .³

The choice of a price for X , or more generally of the degree of repayment to be required, can be made independently of efficiency considerations. The level of repayment can be regarded as a matter of income distribution policy. If Y is aggregate income to project beneficiaries,

$$(8) \quad \Delta Y = Y_2 - Y_1 = B - R$$

where R is the repayment obligation. Let \bar{P}_x be an arbitrary price which is or might be established by the authorities, and which is not necessarily consistent with (4). Authorities can therefore express repayment as a lump sum, R , or in terms of project revenues, $\bar{P}_x X$.

The relationships among the aggregate variables can be illustrated in Figure 1. Project scale as measured by X is plotted on the horizontal axis and various quantities in dollar terms are plotted against the vertical axis. The demand curve, D_x , is also the VMP_x curve. The marginal cost curve is a long-run curve. The optimum scale, X^* , is given by the intersection of the MC_x and D_x curves. The two vertical lines at X_1 and X_2

² Assume secondary or spillover benefits are zero. If secondary benefits exist they can be incorporated here and in the later section, the only problem being measurement.

³ This is not meant to minimize the potential of price or user charges to achieve a rational allocation of resources.

FIGURE 1. INCOME, EFFICIENCY, AND PROJECT SCALE

mark the range of possible project scales within which net benefits are positive, i.e., the benefit-cost ratio is greater than one.

The concave curves marked \bar{Y} are isoincome curves. Their shapes and properties were deduced by taking the total differential of (8) with respect to \bar{X} and \bar{P}_x and setting it equal to zero.⁴ Each curve represents those combinations of \bar{X} and \bar{P}_x which will maintain the same level of aggregate income to project beneficiaries. The maximum possible income occurs when \bar{X} is provided free and its marginal product is driven to zero, assuming, of course, the \bar{P}_x is limited to nonnegative values. Figure 1 also contains isorepayment curves which are defined by the condition that:

$$(9) \quad R \equiv \bar{P}_x \bar{X} = k.$$

⁴ Substitute $R = \bar{P}_x \bar{X}$ in (8). Then:

$$\begin{aligned} \Delta \bar{Y} &= f(\bar{X}, \bar{P}_x) \\ d\Delta \bar{Y} &= \frac{\partial \Delta \bar{Y}}{\partial \bar{X}} d\bar{X} + \frac{\partial \Delta \bar{Y}}{\partial \bar{P}_x} d\bar{P}_x = 0. \end{aligned}$$

The slope of a curve is:

$$\frac{d\bar{P}_x}{d\bar{X}} = - \frac{\partial \Delta \bar{Y} / \partial \bar{X}}{\partial \Delta \bar{Y} / \partial \bar{P}_x} = \frac{P_x(\bar{X}) - \bar{P}_x}{\bar{X}} = \frac{VMP_x - \bar{P}_x}{\bar{X}}.$$

The slope of each curve where it cuts D_x is zero.

As can be seen in Figure 1, if the most efficient project scale is chosen, incomes can be increased as repayment is lowered to zero. Beyond this incomes can be increased only by increasing project scale. At any given R , incomes increase with project scale up to a point; and if \bar{P}_x is fixed, income to the group is at a maximum if project scale is expanded to the point where \bar{P}_x is equal to the demand price $F_x(X)$ given by the inverse demand function (4). To choose from among these possibilities, the planner needs some form of ranking function.

II

Stephen Marglin has considered the problem of project design when income redistribution objectives are present [5, pp. 62-86]. He assumes that the redistribution ranking function compares projects on the basis of their contribution to the aggregate income of a group or region. The group is worthy in some sense, presumably because of low present incomes. In other words larger increments to group income are preferred. He also assumes that the price, \bar{P}_x , is established by a higher authority on the basis of prevailing attitudes toward giving away goods, subsidies, and transfer payments [5, pp. 69-70]. There are three ways in which the criterion for design can be expressed.

The first alternative is to maximize net benefits, N , subject to the constraint that the income to the region, ΔY , be equal to some target level. Alternatively, the constraint could be on N with the objective of maximizing the income to the group. In either case the constraint and the fixed value for \bar{P}_x are sufficient to determine optimum project design as can be seen in Figure 1. The third alternative is to weight efficiency benefits and project incomes, the weighting system to be chosen by the planners. The criterion becomes the weighted sum of N and ΔY . Again, given the weights and \bar{P}_x a unique solution is obtained.

But as presented by Marglin, the design problem seems artificially formulated. The redistribution constraints or weights are variables to the planner but the price is not. Furthermore, the solution to the problem is extremely sensitive to the values of the constraints (or the weights). Marglin suggests that the design procedure might be iterative. The marginal opportunity cost of satisfying the constraint (the Lagrangian term) can be determined, and if judged to be too high, the constraints can be lowered and the project redesigned [5, p. 78]. However, this process involves some rather poorly defined subjective judgments regarding weights and opportunity costs. If subjective judgments are to be made concerning the welfare values of incomes to groups and the opportunity costs of achieving constraints, these judgments should be made explicit and within the framework of a well-defined welfare function. The purpose of the next section is to propose a more general form of

design criterion which is derived from a social welfare function and which will provide guidance in the determination of repayment policy as well as project scale.

III

Planning and selecting projects on the basis of their impact on the distribution of income implies that there is a social welfare function capable of evaluating alternative distributions. Planning could be improved if the welfare function could be specified and incorporated explicitly in the project ranking function. It is assumed here that such a welfare function has been provided to planners and reflects society's assumed preference for more equality of income distribution. What would it look like? To be realistic and to reflect our apparent desire for greater, but not complete, equality of income distribution, it would have to have either an unusual form, or be accompanied by some sort of constraint which prevents the achievement of equality.

Let us assume that total social welfare or social utility is the sum of the contributions of each individual to social welfare and that each contribution to social welfare as opposed to individual's utility is a function of that individual's income alone. The social marginal welfare functions for all individuals are alike, cardinal, and downward sloping functions of individual income.⁵ In other words increments to incomes for different persons are weighted or given different values according to the initial levels of individual incomes. If W is aggregate social welfare, and Y_i is the net income of the i th individual,

$$(10) \quad W = W(Y_1, Y_2, \dots, Y_n) = \sum_{i=1}^n W(Y_i).$$

It obviously follows that social welfare is at a maximum, given the size of aggregate income, when all incomes are equal. But if there is some constraint on the use of taxes and transfers, equality will not be achieved. This constraint could be due to some ethical or moral disutility involved in the taxing process, or due to incentive costs or administrative and deadweight costs of taxation. Whatever the explanation of the constraint, it prevents achievement of income equality through taxes and transfers. In that case, the social welfare function has relevance for project design; and projects can be chosen which will add to social welfare by increasing aggregate income, by redistributing it, or by some combination of both.

The choice of the form which the social welfare function should take is a value judgment; and the economist has no special competence in

⁵ This borrows from Meade's suggestion that individuals could be assigned social welfare weights [6, Ch. 7]. The problem of social welfare functions and project planning is discussed by Eckstein [1, pp. 440-48].

making such judgments. Eckstein has suggested two possible courses of action for economists who want to get on with the important policy issues.

The economist can . . . feel free to perform experiments in policy evaluation using specific objective functions, treating the results as free of absolute normative significance. For example, he can assume a certain shape for the marginal utility of income functions. He may choose to use a form of the function that has been implicitly produced by the political process. The effective marginal rates of the personal income tax at different income levels can be interpreted as implying a marginal utility of income curve. If the government is assumed to act on the principle of equimarginal sacrifice, then marginal effective tax rates can be the basis for deriving a measure of the government's notion of marginal utilities of income [1, pp. 447-48].

The suggested approach is appealing. But the case for using the marginal effective tax rates is wrong. It is clear that the government does not really act on the principle of equimarginal sacrifice. If the government did act on this principle, all incomes above some level (assuming identical social marginal welfare schedules) would be taxed away, and no taxes would be levied on incomes below that level. More importantly there is no unique correspondence between the social welfare function and the tax schedule. Under our assumptions the tax rate structure would be determined not by the social welfare function alone but by the combined effects of it and whatever constraints there were against full use of the tax-transfer system.

Figure 2 represents a society of two individuals. The social welfare function produces a set of isosocial welfare curves, W_1 , W_2 , etc. Point B represents the initial income positions of the two individuals before redistribution. If there is no barrier to using taxes and transfers in pursuit of the social optimum, the line ABC is the "transformation curve" for income distribution, and the optimum is complete equality. The marginal tax rate on income above Y_1 is one. If redistribution is impossible for institutional reasons, the transformation curve is $E'BF'$ and the marginal tax rates are zero. If there is an increasing deadweight or other cost to using taxes and transfers, the transformation curve is EBF . Complete equality of incomes is not the optimum, and the optimum marginal tax rates depend on the marginal social cost of transferring income as well as on the welfare function.

In summary, an increasing marginal effective tax rate does imply a downward sloping social marginal utility schedule, if there is an increasing cost to using taxes for redistribution. However, the shape of the marginal tax schedule has no more claim for recognition as a social welfare function than any other assumed function. The ensuing discussion would be easier to follow if a particularly simple form for the social wel-

additional assumption that individuals have constant marginal utilities of income in order to make (5) and (8) valid measures of B and ΔY .

It is clear that this criterion is a marked improvement over those proposed by Marglin because it explicitly takes into account the original levels of income of the beneficiaries as well as the way the benefits are distributed within the group. But it also requires more information. Planners have to know the initial income distribution and how increments to income will be distributed. They also must be provided with a value for a . For convenience assume that project net incomes are distributed in proportion to the original incomes of the beneficiaries, and that each individual's share of income is known:

$$(13) \quad Y_{i1} = h_i Y_1$$

where

$$\sum_{i=1}^n h_i = 1$$

and

$$(14) \quad \Delta Y_i = h_i \Delta Y.$$

To the extent that beneficiaries do not pay the full cost of the project, there is a subsidy from another group presumably taxpayers, to the beneficiaries.⁶ The subsidy is:

$$(15) \quad S = C(X) - R.$$

And if the distribution of the subsidy cost is known, an individual's share of this cost is given by:

$$(16) \quad S_j = t_j S \quad \text{where} \quad \sum_{j=1}^m t_j = 1.$$

Equation (12) can be simplified if it can be assumed that S_j is very small relative to Y_{j1} , the initial income level of the payer. Then the social marginal welfare of income can be treated as constant over the relevant range and the welfare cost of raising a subsidy is:

$$(17) \quad \Delta W = \sum_{j=1}^m t_j S Y_{j1}^{-a} - bS \quad \text{where} \quad b = \sum_{j=1}^m t_j Y_{j1}^{-a}$$

i.e., the marginal social cost of raising the subsidy is b .

⁶ The subsidy may be paid by other groups besides taxpayers. For example, in the case of reclamation projects some of the subsidy may be paid by the consumers of electric power produced from multipurpose projects, or from other projects in the same river basin. Such subsidies arise when the prices charged for power exceed the costs and the difference is used to reduce the repayment obligation of farmers.

The design problem under these conditions is to maximize the contribution to social welfare made by the project or:⁷

$$(18) \quad \text{maximize } \Delta W = \sum_{i=1}^n \int_{Y_{i1}}^{Y_{i2}} Y_i^{-a} dY_i - bC(X) + b(R).$$

The two policy variables are X and R . The first order conditions for a maximum are:

$$(19) \quad VMP_x \cdot Y_2^{-a} \sum_{i=1}^n h_i^{1-a} - bMC_x = 0$$

and

$$(20) \quad Y_2^{-a} \sum_{i=1}^n h_i^{1-a} - b = 0.$$

The interpretation of (20) is straightforward. The marginal social cost of the subsidy must equal the marginal social value of an extra dollar of income divided among project beneficiaries in the way given by (14). When this condition is substituted in (19), the optimum scale of project for redistribution purposes is shown to be the efficient scale of project as well.

$$(21) \quad VMP_x - MC_x = 0$$

But this happy result stems from the lack of a constraint on R . R must be able to take on negative values, if need be to assure that incomes are raised or lowered to the optimum level.⁸ Note also that the efficient scale of project could have negative net benefits. Thus if

$$(6) \quad N = B - C$$

were the criterion, it would not be built. But such an apparently undesirable project might nevertheless make a positive contribution to social welfare as measured by (18).

If partial repayment is required because of institutional or legal factors, and R is an increasing function of X , there is only one policy variable. The condition for a maximum of (18) is:

$$(22) \quad Y_2^{-a} \sum_{i=1}^n h_i^{1-a} \frac{1}{b} = \frac{MC_x - R_x}{VMP_x - R_x}$$

⁷ This assumes that there are no secondary regional effects either in the region of the project or elsewhere; or that if there are such effects they are distributionally neutral. Otherwise additional terms for secondary gainers and losers would have to be added.

⁸ Equation (20) can also be interpreted as determining the optimum repayment policy for projects.

where R_x is the first derivative of required repayment with respect to project scale.⁹ When the R associated with the efficient project scale exceeds the optimum R , i.e., when the marginal social value of income to beneficiaries is greater than the marginal social cost of the subsidy, further redistribution in favor of beneficiaries is desirable. If R cannot be lowered, project scale must be altered to satisfy (22). MC_x must exceed VMP_x . Planners must build projects that are oversized compared with the results of maximizing (6) or (18). And the social marginal welfares cannot be made equal. In other words, if simple dollar-for-dollar transfers from taxpayers as a group to beneficiaries as a group cannot be used to drive the social marginal welfares to equality, project scale becomes the operating variable.¹⁰ At the efficiency optimum the marginal dollar in costs produces one dollar in benefits, and at a given R , one dollar of income. At a larger scale of output, the marginal dollar of taxes given a social value, for example, of one dollar produces less than one dollar of income, say \$.90. If the marginal social value of an extra dollar to beneficiaries at this point is \$1.11 (because they, roughly speaking, are a lower income group), the social value of the extra \$.90 is just \$1.00. The marginal social cost of a dollar of taxes is equated to the marginal social value of the less than a dollar of income produced at a larger scale of output. This conclusion that oversize projects should be built is independent of the form and parameters of the marginal social welfare schedule. It follows from beneficiaries having lower incomes and there being a binding constraint on R .¹¹

There are some reservations that must be entered concerning the optima that result from the solutions to the model. First, the marginal conditions of (19) and (20) and (22) apply to group "weighted" averages rather than to social marginal welfare changes for all individuals. A low mean income for a group could mask substantial intragroup inequality. It has been assumed that the within-group distribution of benefits cannot be affected by planners. This is consistent with the general assumption barring increased use of taxes and transfers. It accurately describes the situation for many types of projects which are likely to involve distribution considerations, for example, reclamation and flood control.¹²

⁹ If R is fixed as a constraint, independently of project scale, the R_x terms drop out. The conclusion is unchanged.

¹⁰ Project design, as opposed to financial arrangement, is affected by the introduction of redistribution criteria only when \bar{P}_x (or R) is constrained above the value given by (19) and (20). Marglin's assumption that price was given is consistent with our results [5, pp. 69-70].

¹¹ There is another way to explain this oversize. Resources are, in effect, valued differently depending on who owns them. The welfare weighting system as applied to project design is analogous to using two price sets. The marginal cost curve drawn in Figure 1 reflects the market prices for resources used in construction. The resources raised by taxation have a lower social opportunity cost. This lowers the "social" marginal cost curve.

¹² The provision in Reclamation Law limiting the size of farms on federal projects to 160

The second reservation concerns the requirement to build oversized projects. Building oversized projects involves an unmet opportunity cost or cost of insisting on repayment above that defined by (20). This cost is in the form of net benefits foregone. For example, assume $R=0$, and let ΔY_2 be the income of beneficiaries at the optimum scale, and ΔY_3 be the income from an oversize project with output X_2 . Figure 1 shows the essentials. If the efficiency maximizing scale of project were built, the beneficiaries could be made as well off as under the oversize project by a lump sum transfer equal to ΔY_3 minus ΔY_2 . This payment would be raised from the taxpayers and would be equal to the area under the demand curve between X^* and X_2 . This payment would be smaller than the alternative burden on taxpayers which would result from building the oversize project. This latter burden is the area under the MC_x curve between the two alternative scales of the project. The unweighted opportunity cost to society of building at X_2 is the reduction in net benefits from the maximum obtainable, or the area bounded by MC_x , D_x , and the vertical line through X_2 .¹³

When the constraint is binding and oversized projects are built, the result is really a second-best solution in the sense that if one set of marginal conditions (in this case on social welfare contributions) cannot be met, the optimum solution requires divergence from another set of marginal conditions as well. The situation resulting from maximizing (18) is not the most desirable outcome since by reducing project scale and using transfer payments the income of one group could be increased without reducing that of the other group. The second-best solution resulting from this model can only be justified if a third element of social welfare is recognized. If outright grants and transfer payments are deemed undesirable because they are "destructive of moral fiber" or whatever, society must turn to more subtle ways of altering the existing distribution. There is ample evidence that we, as a nation, prefer to hide our subsidies and grants behind a facade of respectability. The requirement of repayment for irrigation projects as currently administered could be interpreted as such a facade for hidden redistributive devices. This preference for covert rather than overt redistribution is an economic good in that it cannot be satisfied without cost.

Although the social welfare function was here assumed to have a particular form for purposes of exposition, the results hold for any welfare

irrigable acres could be viewed as an attempt by policy makers to affect the within-group distribution of benefits. Aside from the opportunities for evasion, the acreage limit does not achieve this purpose. If a farmer is required to sell excess land holdings he will still capture the benefits since they will be capitalized in the price of the land.

¹³ Counting the opportunity cost in the design criterion (18) would result in a smaller, but still oversized, project. The degree of oversize would depend on which group, taxpayers or beneficiaries, was assumed to bear this cost, and the social marginal utility of income to that group.

function with diminishing social marginal welfare or utility of income to individuals. Maximizing such a social welfare function subject to the constraint that incomes cannot be equalized through lump sum taxes and payments requires that projects and programs be expanded beyond the point where marginal benefits equal marginal costs.¹⁴ The degree of oversize which is required for the social optimum depends on the relative income positions of the subsidy payers and the beneficiaries. If the tax used to finance the subsidy falls primarily on high income individuals, the social cost of money raised by taxes will be low and a greater degree of oversize will be optimum.

The degree of oversize will also depend on the form and slope of the social marginal utility schedule. Of course, the choice of welfare function is a value judgment; but it is one which must be made before this criterion can be applied. A value judgment implying a steep social marginal utility schedule means that redistribution benefits are given relatively greater weight in the criterion, and that the degree of oversize will be greater.

IV

The model presented here represents an attempt to follow through on a recent suggestion by Eckstein, namely to "... interpret the desires of the policy people ... and express them in an analytical form as an objective function," and to get on with "... the establishment of decision-models which will reveal explicitly what actions will maximize the achievement of specified objectives" [1, p. 445]. The federal government is moving rapidly ahead with a wide range of programs which combine investment in human and natural resources with subsidies to beneficiaries. Evaluation of these programs with conventional benefit-cost techniques seems to me to miss the point, since there is implicit in the public discussion of these programs the notion of a social welfare function embodying income distribution in some way. The social welfare function used here and the design criteria based on it are simply meant to formalize these apparently widely held ideas, and to examine their implications for project planning.

MARXISM-HORVATISM: A YUGOSLAV THEORY OF SOCIALISM¹

A Review Article

By BENJAMIN WARD*

A certain complacency tends to creep into Western economists' evaluations of avowedly Marxist works. After all, we are in possession, at least relatively, of the truth, in the form of a correct analysis of the price system, a variety of freely competing theories of growth and an open-minded willingness to adapt our models to the burgeoning flow of empirical results (which are mostly produced under the auspices of the Western analytic framework). From this vantage point it is convenient to treat our Eastern colleagues much as we do our students: those who show a willingness to learn are to be encouraged; the others should be urged to change their majors.

No one, I think, who reads Branko Horvat's book with any care will find it possible to maintain this paternalistic attitude. For this is a serious and original, even though avowedly Marxist, rethinking of some major economic problems of contemporary society. The arguments are cast in a language that is almost wholly intelligible to a "purely" Western economist, and the results present an integrated picture of the economic decision process in an optimal social regime. Naturally enough this regime is essentially socialist; not surprisingly, it bears a more than casual resemblance to Yugoslavia. What is surprising is that it carries a more than expected measure of plausibility—at least to this Western reader.

The next section provides an abstract of Horvat's argument. The language is mine, and a good deal is omitted so as to concentrate attention on the main features of the optimal regime. The sections after that contain commentary on various parts of Horvat's theses. The concluding section includes a description of some Yugoslav reactions.

I. Horvatism

Despite Marx's tremendous intellectual accomplishment, including unusual prescience as to future trends in the development of capitalism, there are two major trends in the twentieth century which were incorrectly or incompletely foreseen by him. The first of these is State capitalism, which may be taken ei-

ther as the highest stage of capitalism or the lowest stage of socialism. Marx correctly foresaw the rise of large-scale organizations. Indeed this rise is inevitable, meaning by inevitability that large-scale organizations are both feasible forms of organization and of superior efficiency to the petty capitalist organizations of a century ago. What Marx failed to see was the class conflict that is inherent in bureaucratic systems of control. Once the bureaucracy is established as a dominant system of economic control, a class is created with an interest in preserving its power and relative affluence against outsiders. As noted above it makes little difference whether such a society calls itself socialist or capitalist. It does, however, make some difference whether it is essentially one big bureaucracy or not, and whether it developed out of capitalist preconditions. Weber pointed correctly both to the efficiency properties of rational bureaucracy and to the importance of rational capitalist calculation as an element in promoting that efficiency. As a consequence of the absence of a developed capitalist rationalism, a bureaucracy imposed on an underdeveloped country will be especially inefficient. However Ludwig von Mises pointed to a vital aspect of bureaucracy which Weber ignored, namely the absence of a basis for rational calculation within a large-scale organization that does not contain internal markets. In addition there are the usual problems of bureaucracy: information absorption and distortion within the hierarchy, the aggregative and therefore rough-and-ready nature of the key highly centralized decisions of the top leadership, the tendency to "pass responsibility up and work down," etc.; all of which make very large bureaucracies very inefficient. The tendency toward concentration thus produces at first a higher and more efficient stage of society, but also contains the seeds of its own destruction as still further growth tends to produce unwieldiness rather than rationality.

The second modification of the classical Marxist picture of social development leads to the assertion of the inevitability of worker control, inevitable again in the sense that it represents a feasible social form whose efficiency is superior to that of the historically preceding form. As to the first aspect of inevitability there is a clear trend toward increasing worker participation in management. Partly as a consequence of the workers' natural inclinations there has been some attempt to establish factory committees in every major revolution from 1848 through the Russian and other revolutions around World War I to those of Poland and Hungary of 1956. Partly as a consequence of the needs of state capitalist government some measure of worker control has been introduced widely in nationalized industries and in Great Britain, Germany, and the United States, among others, during wartime. Partly as a consequence of the initiative of enlightened capitalists, from profit sharing to production conferences it has served to increase efficiency and therefore profits. This broad trend strongly suggests both feasibility and superior efficiency. However it was not likely that full-scale worker control of industry would come first to a developed state capitalist society. What was needed was, first, a revolution to sweep away traditional attitudes and authority in a less developed country, and then a developing trend toward workers' management which preceded the entrenchment of the new bureaucracy. Hence

Yugoslavia provided the first instance of this higher form of society, which realizes for the first time the ultimate Marxian aim of free associations of workers.

So much for background. The next step is to survey the problems of planning economic development in the contemporary context.

To maximize welfare one should maximize the total volume of consumption of any generation, subject to a similar maximization with respect to any other generation. But over a generation (say 30 years) consumption maximization is equivalent to production maximization. This is because the limited absorptive capacity of all economies sets short-run limits to the productivity of investment. Most economies can bring the marginal productivity of investment to zero within half a generation, in the sense that no discarded project is capable of producing a net addition to social income over this period. For nearly all economies this implies a steady increase in the savings ratio over at least the first half-generation. However, the future consumption benefits within the generation are so much greater than the early foregone consumption that rational, goods-oriented consumers will almost certainly choose to increase savings up to absorptive capacity. Thus optimal savings and optimal investment will coincide under this policy.²

If a society had already chosen, in some sense, to get on the maximum growth path this would imply that the marginal disutility of saving is zero. Hence it would decide to stay permanently on this path, since with consumption increasing it is highly unlikely that the marginal disutility of saving would increase. The saving decision must be a collective decision because, among other reasons, a consumer faced with his own present-future tastes and the interest rate does not have enough information to make his decision, because his future real consumption depends on the behavior of other consumers. Consumers in an economy that is off the maximum growth path would surely, if faced with a referendum representing the present-future choices outlined above, choose to get on the maximum growth path.

In an optimal regime, getting on the maximum growth path is only part of the battle. One must also make allocative decisions relating to alternative uses of resources. Two interesting aspects of this class of decisions relate to investment choice. The first is that individual decisions, such as might be made by an enterprise or by a planning board with respect to resources available this year, will be made in the face of a positive interest rate. This is true even though the overall marginal productivity of investment is zero because of the partial, short-run context of these decisions. For example, output this year could be increased by putting engineering students to work in factories. The other point is that once society has chosen the maximum growth path the supply of capital over that generation is fixed by that decision. This implies that interest, which may be nonzero for decentralized decision making, is a rent.

The most useful way to treat factors of production when dealing with the problem of designing an efficient economic system is to think of them as the collection of influences on the productivity of labor. It is also useful to distinguish the four traditional factors—monopoly, labor, capital, and entrepreneur-

² For Horvat's illustrative calculations see table in fn. 4.

ship—because of differences in the nature of their impact on productivity. The term “monopoly” is substituted for the traditional “land” to reflect its modern generalization to the surplus over the minimum supply price of a factor. If land is socially owned its minimum supply price is zero, suggesting the Single-Tax (but not alone) as a useful means of controlling income distribution without distorting efficient outcomes.

The search for a welfare economics based on the notion of Pareto optimality has proved a failure. It becomes a defense of the status quo on efficiency grounds, because of the income redistribution that occurs as an inevitable consequence of any readjustment. Hence the controversy and equivocation over the case of increasing returns. Though the broad lines of marginalist evaluation of alternatives remain as useful guides, the full-cost principle is the most satisfactory practical rule of thumb for decentralized decision making by enterprises.

When the above is combined with knowledge of the dangers and inefficiencies of bureaucracy it seems clear that markets are the best “planning authority” for the overwhelming majority of economic decisions. Enterprises striving to maximize profits are the most useful means for organizing the allocative decisions that are not essentially collective in nature.

In an optimal regime enterprises will be controlled by the workers, who will follow the above rule and receive wages as the usual reward for their contribution to productivity. The fourth factor, entrepreneurship, consists in the supply of supervision, coordination, and decision making under uncertainty, combined with Schumpeterean innovative activity. Profit is the supply price of this activity, which in the optimal regime is carried out by the workers’ collective. Since entrepreneurship is diffused throughout the society any particular collective is not entitled to the full profits generated by the market operations of the enterprise.

The optimum distribution of income would be egalitarian, because of the declining marginal utility of income, if income distribution were independent of output. But because of this dependence the rule must be: the most egalitarian distribution of income consistent with maximum production. As societies develop, skewness of the distribution tends to decrease and uneconomic motives to substitute for the individualistic, materialistic incentives of capitalist and underdeveloped societies. It seems likely that before an economy has been on the maximum growth path for many decades the condition attached to the distribution rule will become rather insignificant.

The main features of organization in the optimal regime have already been mentioned. A market economy with socialized means of production is operated by profit-maximizing workers who pay interest-rent, and some portion of profits, to the state for the privilege of operating social capital. They may invest too, but will pay an interest charge on new as well as old capital. They are also charged depreciation in proportion to the amount of capital they operate, and may sell part of their capital to other enterprises, provided they pay back all remaining depreciation charges. A planning authority corrects the market mechanism where necessary to increase economic welfare, by dealing with such problems as externalities, market adjustment failures and income

distribution. These basic organizations will be supplemented by a number of others, such as banks, communes (territorial governments), and industrial associations.

Yugoslavia comes closer than any other existing country to satisfying the conditions for an optimal regime.

II. *Investment Productivity*

The heart of Horvat's policy argument, on which a good deal of the rest depends, is the assertion of the feasibility and desirability of maximizing production over the lifetime of a generation. However a serious problem arises right at the start in giving meaning to the criterion he proposes. Perhaps his clearest statement of the criterion is: "Maximization of welfare of *every* generation means maximization of the total volume of consumption in the lifetime of *any* generation consistent with the similar maximization of *any other* generation" (p. 199; italics his). Nowhere are this criterion or its implications spelled out formally. It appears not to give a decision with respect to investment proposals which increase the consumption of one generation and reduce that of some other generation. However for Horvat's purposes this is not a fundamental weakness. Here as elsewhere in the book Horvat is interested in developing a practical rule for planners. His views as to the actual structure of development alternatives makes the range of indecisiveness of the criterion much less than it appears *in abstracto*. A practical rule can probably be constructed which will satisfy the requirements of his theory and which is not *prima facie* unacceptable. For example consider the following rule: (1) Ignore all investment projects to be implemented in the next or later generations; (2) adopt all investment projects which increase net consumption over this generation and the next. This is obviously not an optimal rule, but two things can be said for it: (1) Its allocative failures are likely to be concentrated in the distant future so that present uncertainty offers little opportunity to improve the decisions before the next plan (a point emphasized by Horvat), and (2) the marginal consumption-productivity (over two generations) of investment is zero for projects implemented in this generation, a key feature of Horvat's approach.³

A much more interesting part of Horvat's theory is the assertion that in effect the opportunity cost (in terms of consumption) of increasing the ratio of investment to output is near zero up to a very high ratio. He argues that a good estimate of the typical marginal capital output ratio is about three, that that ratio tends to be fairly constant with increasing investment ratios up to some ratio near the capital saturation point, provided the investment ratio is not increased by more than one or two percentage points per year, and that capital saturation (absorptive capacity) tends to occur at an investment ratio of around 35 per cent. Consequently a country with a current investment ratio of 15 per cent might rise to the long-run-saturation investment-ratio-point in

³ Unless the actual structure of development alternatives is that hypothesized by Horvat, a rule like this could produce results that were strongly biased against the consumption of some (probably the earlier) generations. In this sense too it is a "practical" and not a "theoretical" rule.

ten years or so, after which output will grow steadily at about 10 per cent per year. If this is true, the investment ratio may be increased without ever producing fewer consumer goods than in the base year and with a growth rate of consumption such that in no year is the consumption level more than a year or two behind the level that would have been achieved had there been no increase in the investment ratio. And long before the initial generation "disappears," say 25 years later, society is consuming far more than it would have under the 15 per cent ratio, as well as growing much more rapidly, and providing a far larger capital base for the next generation.

If the assumptions are true the conclusions do follow.⁴ As with other parts of his analysis Horvat is leaning rather heavily on recent Yugoslav experience, where investment ratios of around 30 per cent have been producing a growth of output of almost 9 per cent for nearly fifteen years. Furthermore, one can find support for at least part of the argument in a recent analysis of prospects during the seven years 1963-70 for some fifty developing countries [6, Annex A] [7, p. 718]. Upper-limit growth possibilities on the average for these countries are estimated at about 6 per cent. Marginal capital output ratios are estimated at 3.2 and the marginal savings ratio at potentially 24 per cent, with investment growing potentially at 10 per cent. Under favorable circumstances and with strongly growth-oriented policies the countries of the underdeveloped world on the whole are apparently, according to an independent estimate, capable of carrying out the early portion of Horvat's program.

It is difficult to get a clear empirical insight into the relation between the size of the investment ratio and the size of the marginal capital output ratio. There is some weak tendency in the data on which the above study was based, which mostly covers about five years during the late fifties, for higher values of the former and the latter to be associated, but there are also a number of exceptions. Data for NATO countries over the years 1950-63 show some tendency for rising investment ratios (and especially for those which are above 20 per cent and rising) to be accompanied by higher marginal capital output ratios, several of them being well above 4.0 [19, Table VI-6]. The Eastbloc countries (excluding Rumania and Albania) had marginal gross capital output ratios of 5.6 (unweighted average) over the period 1951-64, with high in-

⁴The following table (Horvat, p. 190) shows how this works. Pattern I shows consumption and output when the investment ratio is maintained at 15 per cent, Pattern II when the investment ratio increases by one percentage point per year and Pattern III when it increases by two percentage points per year. The underlying assumptions are as stated in the text.

| Year | Pattern I | | | Pattern II | | | Pattern III | | |
|------|-----------|----------|-------------|------------|----------|-------------|-------------|----------|-------------|
| | Output | \$ in | Consumption | Output | \$ in | Consumption | Output | \$ in | Consumption |
| | | per cent | | | per cent | | | per cent | |
| 0 | 100 | 15 | 85 | 100 | 15 | 85 | 100 | 15 | 85 |
| 1 | 105 | 15 | 89 | 105 | 16 | 88 | 105 | 17 | 87 |
| 2 | 110 | 15 | 94 | 111 | 17 | 92 | 111 | 19 | 90 |
| 3 | 116 | 15 | 98 | 117 | 18 | 96 | 118 | 21 | 93 |
| 4 | 122 | 15 | 103 | 124 | 19 | 100 | 126 | 23 | 97 |
| 5 | 128 | 15 | 108 | 132 | 20 | 105 | 136 | 25 | 102 |
| 6 | 134 | 15 | 114 | 140 | 21 | 111 | 147 | 27 | 108 |
| 7 | 141 | 15 | 120 | 150 | 22 | 117 | 161 | 29 | 114 |
| 8 | 148 | 15 | 126 | 161 | 23 | 124 | 176 | 31 | 121 |
| 9 | 155 | 15 | 132 | 173 | 24 | 132 | 194 | 33 | 130 |
| 10 | 162 | 15 | 138 | 187 | 25 | 140 | 216 | 35 | 140 |

vestment ratios. Furthermore, the capital output ratios tended to rise with the investment ratios within this period [10, pp. 890-92].⁵ However, the Soviet Union has apparently had an unusually low incremental capital output ratio despite its relatively high investment ratio [5, p. 357]. Finally, Horvat notes the very large improvement in the postwar Yugoslav ratio and asserts that this is attributable in large measure to improved ability to implement the rapid growth policy. Unfortunately, the change is too easily associated with the stagnation of industrial growth during the period of adjustment to the Cominform blockade to be generalizable. These data *prima facie* call for a good measure of skepticism about capital coefficient constancy with increasing investment ratios, but by themselves are probably insufficient to reject the thesis. There are examples, such as Yugoslavia itself, where high investment productivity and high investment ratio appear to go together, and even where the former is low it may be argued that institutions for economic decision making were inefficient, representing a lower stage of social development.⁶

III. *Macroeconomic Control*

Suppose for the moment that Horvat is right and declining investment productivity as a result of decreasingly attractive alternative projects is not a hindrance to his policy. One question that still must be answered is whether the economy can be moved to and kept at the zero-productivity point.

First the point must be identified. The argument that the point is located at an investment ratio of about 30 to 35 per cent is based on the fact that Soviet-type economies and Yugoslavia have tended to operate near this level, and the assertion that though their investment productivity has not suffered dramatically as a consequence, they have occasionally pushed their investment activity beyond the point of positive return. That is, no empirical support is offered for this part of the thesis. Probably at the margin all the Eastbloc countries, including the Soviet Union, have often been well beyond the zero-investment-productivity point, but they have also probably been missing some good bets for productive investment.

Identification of the point is made more difficult because of the uncertainty surrounding investment alternatives under conditions of very rapid growth. At an 8 per cent growth rate, output doubles every 9 years, so that well within, say, a half-generational planning timespan new projects will have to be integrated with a capital stock over half of which is as yet nonexistent. This suggests that a large margin of error will be attached to investment plans and may lower investment productivity as well as make the sought-for state hard to identify.

A notable if not unexpected feature of the Chenery-Strout study [6] [7]

⁵ These data were recalculated from official statistics by Thad Alton and Associates.

⁶ Together with Horvat we are assuming that these aggregates provide a meaningful basis for policy discussion. For example, because of the variability of the capital output ratios across sectors, Horvat's thesis may hold for a country only if it is willing to accept a structure of investment that may be undesirable on other grounds. Nevertheless for the sort of global orientation toward development policy that Horvat has in mind this level of aggregation appears to be rather useful.

is its finding that the effective constraint to further growth in a large number of underdeveloped countries is balance of payments. Horvat ignores foreign trade, a serious failing from the point of view of the plausibility of his arguments. Its effect in the present context is implicitly to assume that every country will be able to obtain aid of a sufficient magnitude to move the economy out to the absorptive-capacity constraint. For a Marxist, especially, that is a rather naive assumption.⁷

A final question has to do with the instruments for achieving Horvat's goal. In his optimal regime, state policy will assure a high level of aggregate demand. The problem is that we are still in an early stage of our understanding of short-run macro-economic control techniques, and less developed countries with their greater structural rigidities are probably much harder to control than, say, the United States. At high growth rates control problems are more serious, the risks of overheating are large, and the cost in output foregone during adjustment can be fairly high. This question is essentially dismissed by Horvat who seems to be at least as good a Keynesian as he is a Marxist.

IV. *The Optimum Rate of Savings*⁸

The really striking thing about Horvat's calculations (see the table in footnote 4 above) is their implication of a near zero opportunity cost, in terms of aggregate consumption, for higher growth up to a very high rate. In Patterns II and III, after a decade one gets more consumption forever than in Pattern I, so there is no long-term cost to choosing maximum growth. In the short run there are a few years in which consumption increases lag behind in Patterns II and III, but the lag never exceeds a year or so, is usually less, and absolute consumption never falls.

This peculiar consequence of the compound interest formula has been known for some time. A variant of the thesis was, for example, offered by Peter Wiles some years ago [24].⁹ But so far as I know Horvat is the first writer who both uses this consequence to defend maximum growth of output and tries to offer an integrated theory to support the realization of the goal. The undoubted power of compounding to produce amazing increases in output over a generation or two lends added interest to the question: Given that Horvat has the facts right, is his policy proposal desirable?

To part of the question the answer in terms of the usual assumptions is a simple "yes." Suppose (1) that a society's decisions are governed by the morally appropriate social welfare function, (2) society is on the maximum growth path, and (3) is in an equilibrium state. Then clearly it should stay on that path. For in equilibrium the marginal disutility of saving is equal to the mar-

⁷ Horvat also ignores population growth. However when economies start growing steadily at ten per cent, a population growth rate of three per cent or so will not cause great alarm, though problems of adaptation to the changing factor mix may arise.

⁸ Issues surrounding this question are most lucidly analyzed by Sen [22]. Sen deals with Horvat's maximum-output proposal explicitly, as the proposal was initially presented in 1958 [14]. Horvat has recently returned to its defence [16].

⁹ A very early absorptive-capacity growth model was developed by the Soviet economist, G. Fel'dman [11]. A translation of his paper is available [23] and Domar has analyzed it [8].

ginal utility of investment (in terms of additional consumption produced by the investment). The marginal utility of investment is zero on the path and with consumption rising the disutility of saving will not rise. Hence society should stay on the path.

Objections may be raised against this position on three grounds. First there are some who argue that over certain ranges the marginal utility of income rises, in which case the marginal disutility of saving may in principle rise with income. Not an important objection, I think, especially since this phenomenon cannot dominate a broad range of incomes. Secondly, and more importantly, if one believes that Pareto optimal savings can be generated by independent market decisions of households, it seems clear that the argument breaks down, because the second condition above seems in fact never to occur in societies where this form of savings mobilization dominates. Thirdly, and still more importantly, it is not clear, except in the most simplistic cases, that conditions (1) and (3) can be given an intelligible meaning when one does not believe that independent decisions are consistent with a Pareto optimal savings rate.

The argument against independent-decision optimality is strong and is based essentially on the individual's inability to determine the future availability of goods to himself without knowing the intentions of others, and on his interest in a future that extends beyond his own lifetime. Future prices depend not only on the individual's saving decision, but on the current intentions of all other potential savers. The market gives highly incomplete information on the productivity of current saving and on expected future prices. As to the second point, an individual may not be willing to save a dollar now to produce three dollars after he is dead, but may be willing to do so if someone else agrees to do the same. Then, in effect, he has produced six dollars of income for future generations at a cost of a dollar of saving to himself and a dollar of current loss to "his" generation.¹⁰

Thus a collective decision seems necessary to achieve Pareto optimality. The trouble is we have no joint decision processes which produce Pareto optimality in the absence of consensus. The referendum that Horvat proposes can in principle produce a result which makes a large minority extremely unhappy. A political equilibrium does not in general have economic optimality properties.

The remaining part of the question is in a way easier to deal with. If the cost of moving to the maximum growth path is very small and the gain is very great, then presumably most everyone will want to do it. That is, Horvat might argue that up to now people have not been sufficiently informed as to the costs and benefits of this choice, so past empirical data are irrelevant, and the benefits from choosing maximum growth are so great that objections of the kind raised above are swamped.

Where does all this leave us? It leaves me, at least, in the following position: (1) The attractiveness of compounding is very great and creates a predisposition toward higher growth; (2) available data indicate very crudely that

¹⁰ These are Sen's arguments, *q.v.* Reference might also be made to James Buchanan's argument that condition (1) may be unintelligible even (rather, especially) with independent-decision optimality.

underdeveloped countries typically can raise their gross investment ratios substantially, for example to 20 per cent or more, with little cost in terms of gross investment productivity, provided an adequate (which usually means substantial) availability of foreign aid is assured. (3) This could get growth rates of output to above five per cent but in most cases (on the average over a long pull) probably not too much above that rate. (4) In terms of economic control the above will not be easy to achieve and for higher rates the costs, including the risks of dramatic readjustments, will be excessively high in most cases. (5) Socialist experience, including the Yugoslav, suggests that these risks tend to be shifted by the planners and their bosses to the consumption sector, and that this produces a very different consumption timepath than the neat monotonic patterns in Horvat's table.

V. Neoclassical Planning Theory

A problem of interpretation makes the evaluation of Horvat's decision calculus a needlessly difficult job. He is very critical of the received western doctrine in the area of resource allocation, generally ending up by dismissing the theories as valueless toying with trivial cases. However, this is frequently followed by the proposal to use a much cruder version of the same theory, whose validity perforce is proved only for even narrower and less realistic situations. A striking instance is his detailed criticism of marginal cost pricing, followed by the claim that profit maximizing is the best way to deal with enterprise allocation decisions.

There is, I assume, nothing inconsistent in this. Rather, Horvat is simply saying that in practice the fancier aspects of economic theory can be ignored because data and administrative problems do not allow control or even observation of such fine distinctions. However, given that this is his purpose, the attacks on economic theory are needlessly polemical.

Essentially Horvat accepts the current western doctrine that the market system works effectively and should be left to do the job except where paternalism, monopoly, and neighborhood effects occur, or a bad distribution of income results. In these cases Horvat and Milton Friedman recognize in principle the legitimacy of state intervention. Nevertheless there is a real difficulty with much of Horvat's argument which is probably a result of the form of presentation. He is extremely casual both in his factual assertions and in his discussion of proposed remedies for the failures of the market. Probably most economists would agree with his preference for the real market over administrative simulation of markets. But no one will be convinced by the brief comment he devotes to it after a harangue on the inadequacies of marginal cost pricing. His position in a nutshell seems to be: The market knows best, except in cases where society knows best. However, he devotes little attention to problems of decision making in cases where the market fails. He seems to be saying that where the market fails the economist does too. "The examination of how social valuations are arrived at falls outside the field of economics" (p. 32). This important class of decisions is turned over to the planners, along with a general social criterion, but no guidance is offered as to what to do with them.

In discussing factors of production, Horvat fails to mention one of the most useful attributes of market allocation: the assignment of distinct functional returns to the various factors. Perhaps there is good reason for this omission, since under worker management the separation of profits and wages is no longer performed by the market. Surely this can cause serious administrative difficulties, but they go unmentioned, along with those that would be associated with his proposed tax on nonwage quasirents. His discussion of entrepreneurship as a factor seems to be more a doctrinal than an economic theory, and seems to be aimed mainly at proving that society, being in part the entrepreneur, has a right to a share of enterprise profits.

Within their generational time horizon planners must choose which specific projects to approve and when to schedule their implementation. This is a most difficult and fundamental type of decision but Horvat's highly aggregative growth theory, his incompletely specified maximization problem (see p. 513 above), and his essentially polemical discussion of the interest rate offer little assistance in solving it. The informational activity that will be needed to produce the optimal ten or fifteen year bill of investments is surely beyond the capacity of any existing agency. Or will the market determine most of this? Presumably in most underdeveloped countries the answer to the latter question is: "no," which means placing the economy's future in the hands of an assertedly extremely inefficient bureaucracy. But even where it is "yes," what assurance is there that worker managers will behave in the appropriate ways? It is not even clear that they will be profit maximizers. The first sentence of the English foreword begins: "This is a book of a planner for . . . planners. . . ." Surely a theoretical framework to deal with these problems is called for, and would be more valuable even to a theoretical planner than attempting to shoot down once again Frank Knight's views on the interest rate.

VI. *Horvat as a Marxist*

In his value theory Horvat manages to produce more or less Marxian results from more or less neoclassical assumptions. He defines the marginalist calculus as a tautological system which is incapable of being falsified, so presumably he accepts it as a logically consistent, if in principle uninterpreted, theory. The labor theory of value, as a specification or special case of the marginal calculus, is capable of being falsified. This is a tenable position, sanctioned in fact by Schumpeter, though it is not the only tenable position. Surely there are a variety of ways in which marginalism can be given a real world interpretation, in the sense that some of its propositions can be so interpreted as to be conceivably falsifiable as a result of empirical test. However, there seems to be no logical or methodological reason why Horvat's approach need be rejected.

An advantage of his approach is that the long, bitter, and largely empty discussion of the applicability of Marxian price and value schemes to socialism is bypassed. Taking Marx's *en passant* ". . . I have never built a 'socialist system' . . ." [18, p. 357] as text, Horvat can point to the usefulness of the labor theory in some contexts and go on to the tautological and hence ideologically neutral marginalist calculus as his starting point. The next step is to

provide a new specification of that calculus to apply to the planned economy.

The maximum growth policy has an important implication for this calculus. Once the optimal amount of investment over the generation is chosen, decisions still remain as to the timing and more specific properties of individual investment projects. Some proportion of these decisions will be decentralized and a nonzero interest rate will probably enter into the calculations of the decentralized units. But since variations in this rate will not change the amount of capital forthcoming over the generation (though it can lead to changes within shorter time periods), and since the marginal productivity of investment over the generation is zero, all such interest charges are in the nature of a rent, from the point of view of the generation, and will be captured by the state. Thus one famous Marxian dictum is satisfied. Horvat's approach is novel in detail though the strategy is a hoary one.¹¹

The state captures all other nonwage quasirents too. This leaves labor and entrepreneurship as factors receiving functional shares. But the latter is a kind of labor and in the optimal regime accrues only to laborers, so in a general sense value is exclusively created by, and functionally allocated to, labor. Hence, though pricing is conventional, the moral content behind labor value theories is satisfied in Horvat's scheme.

If all Eastbloc economists were to accept this approach they would no doubt find it a good deal easier to discuss alternative price systems. However, Horvat has not made much use of the opportunity he has created. He does not discuss the administrative problems associated with price regulation in either a socialist or a state capitalist economy, aside from asserting that a market mechanism, based on profit maximizing as the incentive, does the best job in most cases. Nor does Yugoslav experience suggest that this problem will not be very troublesome in the socialist stage of society. Perhaps some more sophisticated versions of the theory will prove to be useful after all.

Horvat's sociological Marxism is most clearly exemplified in the twin propositions that state capitalism and worker management are the successively higher postcapitalist stages of society. The superior-efficiency aspect of their "inevitability" can be questioned in both cases. On the first of these assertions especially there is a gap in Horvat's argument. There is a good deal of discussion of the efficiency of bureaucracy as compared to small scale organization, but essentially the claim to superior efficiency of state capitalism rests on the assertion that, as a consequence of planning, growth rates are doubled or trebled. As empirical descriptions these figures are somewhat exaggerated but, quite aside from this, it may well be that higher growth is not really a consequence of bureaucracy but of the use of macro-economic instruments of control in order to maintain a high level of aggregate demand. If this is true, then the simple extrapolation of past trends toward greater concentration may generate false predictions. Apparently concentration ratios in the United States have tended to be relatively constant for three or four decades, larger size of organizations being roughly compensated by the growth of markets [2, p. 206-7].

¹¹Theodor Hertzka [13] is the earliest author I know who marries Marx with neo-classical economics by going to the point of capital saturation. Horvat's innovations are to claim a speedier arrival time and to assert that the saturated state can be maintained in the face of rapid technological change.

And the developing movement toward less centralized decision making in the Eastbloc without a simultaneous move toward worker management¹² opens the door to speculation that this trend is being aborted without a change in stage and with an increase in efficiency.

As for the second proposition, I, at least, find convincing the evidence that worker participation in enterprise decision making has been riding a strongly increasing trend in the twentieth century. What is not convincing is that "full" worker management possesses superior efficiency or that it is a very likely development. First, there are powerful political forces arrayed against the optimal regime, more even than socialists used to find arrayed against other types of socialism, for not only the capitalists but the trade unions are threatened by this development, as Horvat points out quite clearly. Secondly, there is really no mechanism for the collapse of state capitalism, especially since total bureaucratization does not seem a particularly plausible end result for that regime, but also because buying off of the workers is an accepted bureaucratic-capitalist strategy. Compromise is a poor substitute for deepening class conflict. Thirdly, the superiority of his optimum regime is not established. Administrative problems with the scheme have already been mentioned. But even if Horvat is right about the optimum growth path, he ought to be able to convince the state capitalists that they should adopt it, for it is a genuinely Pareto optimal solution in the sense that in principle everyone can gain from moving to that policy.

Finally, there is at least one possible alternative "next higher" stage which can substitute for state capitalism. There is no time to discuss it here, but it might be called "regional monopolism" and emphasize the great and apparently still growing relative differences among regions of the world. Standing in the way of the eradication of these differences are some of the world's most powerfully entrenched institutions, the affluent and militarily powerful nation states.¹³ Paths to a "revolutionary transformation" of this collection of institutions are perhaps somewhat easier to find (nuclear war, for example). At any rate, Horvat's optimum regime offers no answer to the problems posed by this situation. Indeed, the example of Yugoslavia suggests that regional conflicts are not well mediated by that approximation to the optimal regime even when regional interests are not defended by sovereign states. The synthesis just does not emerge here.

VII. *Conclusion*

Horvat's views have come under sharp criticism in the Yugoslav press.¹⁴ His use of "bourgeois" concepts and the "ahistorical" application of norma-

¹² So far at least. However, Gregory Grossman has argued [12, p. 55] that political pressures for more worker autonomy within the enterprise will probably follow decentralization.

¹³ Had he recognized the similarities between the Soviet Union and the United States on this dimension, Paul Baran would perhaps qualify as an adherent to this position by virtue of his well-known work on the political economy of growth [4].

¹⁴ These comments are based on two review articles [9] [20], a discussion of Horvat's theories of value and of planning, as presented by him to a conference in Yugoslavia [17] [21], and a discussion of his high-growth thesis as applied to Yugoslavia by a number of economists in the report of a conference [1].

tive theory to the discussion of such economic phenomena as prices have come under especially heavy fire, as has his use of a lone quote in throwing over the traditional Marxian value formalisms. It would seem that, in the early sixties no less than in the early fifties, Yugoslav ideologues are not prepared to accept attempts at "bridge building between the labor theory of value and the utility theory of value."¹⁵ However, in response, Horvat gives not an inch; indeed, there is a strong flavor of the "critique of the Gotha Program" in the tone of his reply to Pirec [15, pp. 272-74].

The combined proposal for more decentralization of allocative decision making with an increase in the already very high investment ratio also failed to strike a responsive chord in the Yugoslavia of early 1963, when a slackening in the growth rate led many economists to support a relatively greater emphasis on consumption plus decentralization. Probably this portion of Horvat's thesis would have found a more sympathetic audience two years earlier; perhaps also two years later. In this case, too, Horvat was not prepared to concede, and his own unmodified views have been published in several places.

Horvat's work represents a big step forward as compared to current Marxist writing with which I am familiar. One finds in Horvat neither the ritualistic obeisances to the classics and heroes of Soviet ideologues, nor the vapid emotionalism of many socialist humanists, nor the angry negativism of much of the American New Left. The arguments are usually incisive, intellectually challenging, but nonetheless couched in an aggressive style that Marx himself might have appreciated. True, attention is devoted to a discussion of the two highest stages of society (with even a glimpse or two into the more distant future), but, his Yugoslav opponents to the contrary, this does not qualify as utopianism, for Yugoslavia is assertedly a socialist country, an optimal regime. If Marxists who disagree with Horvat were to present alternative positions in as constructive a vein, Marxism might once again become a living body of thought.

Market Structure and the Employment of Scientists and Engineers

In the December 1965 *American Economic Review*, I reported results unfavorable to Professor Schumpeter's conjectures regarding the relationship between monopoly power and technological innovation [4, pp. 1117-21]. An analysis of 48 narrowly defined manufacturing industries revealed no significant tendency for the output of the industry leaders' 1954 patented inventions to increase with the industries' 1950 four-firm concentration ratios, *ceteris paribus*. Here I shall extend the analysis, utilizing data from a new and more comprehensive sample.

I. The Data

The hypothesis tested is that industrial inventive and innovative effort, measured by the employment of technical engineers and scientists, increases with the concentration of market power, other relevant variables such as total industry employment, technological opportunity, and product characteristics being held constant. Three dependent variables were used. One is the number of technical engineers E_i plus natural scientists S_i employed in 56 manufacturing industry groups during 1960. The second is the number of natural scientists S_i only (averaging 14 per cent of total technical employment $E_i + S_i$). Estimates of both E_i and S_i were obtained from a five per cent sample of the 1960 Census of Population [6].¹

The third dependent variable requires more explanation. Although production engineers, quality control mathematicians, and similar personnel are undoubtedly responsible for some inventions and innovations [1][5], the prime source of new industrial technology is presumably the formally organized research and development laboratory. But only 45 per cent of U.S. manufacturing industry's scientific and engineering employees during 1960 were engaged in formal R&D work [8, p. 25]. Furthermore, only 57 per cent of (nonaircraft) industry's R&D effort was supported with private funds, and hence subject to the market incentives to which Schumpeter's market structure hypotheses are solely applicable [7, p. 65]. Consequently, a third estimated private research and development employment variable $RD_i = (F_i)(P_i)(E_i + S_i)$ was defined, where F_i is the proportion of the i th industry's scientific and engineering work force engaged in formal R&D and P_i is the fraction of the industry's R&D financed privately.²

¹ The engineering employment variable excludes sales engineers, while the scientific employment variable includes mathematicians. Three "not specified" catchall groups were excluded from the sample. In addition, the aircraft and shipbuilding industries were left out because their technical activities lie for the most part outside the private market sector, and newspaper publishing was excluded because of its peculiar product and market characteristics.

² Data on F_i and P_i were obtained for 13 and 19 broader industry groups respectively from [8] and [7]. These ratios were applied, after a few adjustments based upon supplemental knowl-

The definitions of the 56 industry groups sampled (covering nearly all of U.S. manufacturing industry for 1960) were governed by the availability of data. Classification problems forced the Census Bureau to use a heterogeneous system in aggregating the occupational data by industry. The industry groups ranged from narrow clusters of one or a few four-digit S.I.C. industries (i.e., synthetic fibers) to quite broad two-digit sectors (i.e., electrical machinery, equipment, and supplies), although most were at the three-digit level of aggregation. It was therefore necessary to use a weighted average index of concentration as the independent variable of primary relevance to the hypothesis tested. The concentration index C_i of the i th industry group is the average (weighted by value of shipments) of the 1958 four-firm concentration ratios for all four-digit S.I.C. industries included in that group [9, pp. 11-42].

To take into account interindustry differences in scientific and technological opportunity, dummy variables are defined for four broad classes: general and mechanical (G&M), electrical, chemical, and traditional. Each industry group was assigned to one of these classes after analysis of the group's product technology characteristics.³ Choices involving the electrical and chemical classifications were straightforward, but it was difficult to avoid some arbitrary judgments in distinguishing between industries with G&M as opposed to traditional product technologies. In borderline cases, the G&M classification (used as the intercept class in all regressions) was favored.

Three additional dummy variables were used to distinguish durable from nondurable goods industries, consumer from producer goods industries, and industries characterized by local or regional markets from those essentially nationwide in scope.

II. The Model and Tests

If Schumpeter's conjectures are correct, one would expect the absolute differences in technical employment associated with concentration to be greater for large industries than for small. Past experience with similar data has shown that the error terms of untransformed linear regressions on the industry size variable are heteroscedastic, and that observations from extremely large industries can dominate the regression estimates. These theoretical and statistical considerations call for either a multiplicative or ratio specification of the model. In my 1965 article a multiplicative model was chosen to test the concentration hypothesis. With the present sample variables, the model can be written:

$$(1) \quad (E_i + S_i) = aN_i^\alpha C_i^\beta \left(\prod_j 10^{\delta_j D_{ij}} \right) u_i;$$

edge, to the 56 narrower industry groups. The resulting estimates are crude, although there is no reason to suppose that the estimation errors are systematic.

³ The classifications conform closely to those found significant in [4, pp. 1103 and 1107]. A table giving the industry classifications and other raw data used in the study is available upon request from the author.

where N_i is total 1960 employment of the i th industry (scaled in thousands), D_{ij} is a dummy variable with the value of 1 if the i th industry is in the j th technology or product characteristic class and zero otherwise; and u_i is the error term. The dummy variables in this model relate to the slope of the regression hyperplane with respect to both industry size N_i and concentration C_i . This specification implies that as C_i tends to zero, $(E_i + S_i)$ also tends to zero, no matter how high δ_j and N_i are—that is, no matter how large the industry is and how favorable the technological opportunities confronting the industry are. But it seems more reasonable that, in a field as enriched as, say, the electronics industries are with opportunities opened up by the advance of science, many scientists and engineers would be employed even if the industry structure were atomistic. While the specification of equation (1) might serve adequately over the range of concentration values actually observed (the lowest was 10 per cent), the use of an alternative ratio model appears preferable on a priori grounds:

$$(2) \quad \frac{(E_i + S_i)}{N_i} = c + \sum_j d_j D_{ij} + g C_i + v_i.$$

In this form, the influence of interindustry differences operates independently of the concentration level. Even when the industry is atomistic ($C_i \rightarrow 0$) it can have a significant fraction of its work force assigned to scientific and engineering tasks.

Because it appears more consistent with a priori knowledge, I am inclined to favor model (2) over model (1). But since the case for model (2) is not ironclad, and since the conclusions depend to some extent upon the choice of models, I shall first summarize the tests of model (1). Regressions were run in logarithmic form for the three dependent variables on N_i alone; on N_i with C_i ; and on N_i with all dummy variables, with and without C_i . When the concentration variable was introduced into regressions of $\log(E_i + S_i)$, $\log S_i$, and $\log RD_i$ on $\log N_i$ without dummy variables, its regression coefficients were in all cases positive and highly significant, and it made an incremental contribution to the percentage of variance explained (100 R^2) of 25.5, 15.9, and 22.4 percentage points respectively.

The concentration regression coefficients remained positive and significant when all dummy variables (and also subgroups of the dummies) were introduced, as shown in the following equations, where $Elec_i$ is the electrical class dummy, $Chem_i$ the chemical class dummy, $Trad_i$ the traditional product technology class dummy, Reg_i the regional market dummy, Dur_i the durable goods dummy, and $Cons_i$ the consumer goods dummy. Standard errors are given in parentheses under the coefficients.

$$(3) \quad \log(E_i + S_i) = - .03 + .95 \log N_i + .94 \log C_i + .30 Elec_i \\
\begin{array}{ccccccc}
& (.11) & & (.24) & & (.24) & \\
+ .44 Chem_i & - .47 Trad_i & - .05 Reg_i & + .05 Dur_i & & & \\
& (.17) & (.11) & (.13) & (.10) & & \\
- .14 Cons_i; & & & & & & R^2 = .830. \\
& (.09) & & & & &
\end{array}$$

$$\begin{aligned}
 (4) \quad \log S_i &= 1.09 + .95 \log N_i + 1.34 \log C_i + .10 Elec_i \\
 &\quad (.22) \quad (.48) \quad (.49) \\
 &\quad + .63 Chem_i - .54 Trad_i + .14 Reg_i - .67 Dur_i \\
 &\quad (.34) \quad (.22) \quad (.26) \quad (.21) \\
 &\quad - .37 Cons_i; \quad R^2 = .600. \\
 &\quad (.18) \\
 (5) \quad \log RD_i &= - .36 + .93 \log N_i + .80 \log C_i + .27 Elec_i \\
 &\quad (.11) \quad (.24) \quad (.24) \\
 &\quad + .51 Chem_i - .41 Trad_i - .01 Reg_i + .10 Dur_i \\
 &\quad (.17) \quad (.11) \quad (.13) \quad (.10) \\
 &\quad - .09 Cons_i; \quad R^2 = .805. \\
 &\quad (.09)
 \end{aligned}$$

When equations (3) through (5) were computed with the concentration variable deleted, the amount of variance explained ($100 R^2$) fell by 5.5, 6.6, and 4.5 percentage points respectively. Thus, the incremental explanatory power of concentration is much less when dummy variables are included than when the concentration variable is used with industry employment N_i alone. Still all of the incremental variance gains due to including C_i in equations (3) through (5) are significant in F -ratio tests at the 1 per cent level. These results therefore tend to support Schumpeter's hypothesis that inventive and innovative activity increases with market concentration.

Turning now to the ratio model, the simple correlations involving only technical employment, total employment, and concentration also supported the hypothesis, although not as consistently. The r^2 's were .21 between $(E_i + S_i)/N_i$ and C_i ; .19 between RD_i/N_i and C_i ; but only .027 between S_i/N_i and C_i . Introduction of the six dummy variables led to much sharper declines in the explanatory power of concentration than in the multiplicative model. The equations were as follows (with the dependent variables scaled in technical personnel per 1,000 total employees):

$$\begin{aligned}
 (6) \quad \frac{E_i + S_i}{N_i} &= 16.4 + .155C_i + 38.1 Elec_i + 35.7 Chem_i - 14.3 Trad_i \\
 &\quad (.109) \quad (9.0) \quad (6.6) \quad (4.1) \\
 &\quad - 4.6 Reg_i + 4.9 Dur_i - 1.3 Cons_i; \quad R^2 = .728. \\
 &\quad (5.0) \quad (4.0) \quad (3.5) \\
 (7) \quad \frac{S_i}{N_i} &= 5.0 + .01C_i + .36 Elec_i + 25.4 Chem_i - 2.2 Trad_i \\
 &\quad (.05) \quad (4.16) \quad (3.0) \quad (1.9) \\
 &\quad - 1.0 Reg_i - 2.3 Dur_i - .45 Cons_i; \quad R^2 = .715. \\
 &\quad (2.3) \quad (1.8) \quad (1.61)
 \end{aligned}$$

$$\begin{aligned}
 (8) \quad \frac{RD_i}{N_i} = & 4.3 + .054C_i + 8.4 \textit{Elec}_i + 11.9 \textit{Chem}_i - 4.0 \textit{Trad}_i \\
 & \quad (.036) \quad (3.0) \quad (2.2) \quad (1.4) \\
 & - 1.1 \textit{Reg}_i + 1.5 \textit{Dur}_i + .3 \textit{Cons}_i; \quad R^2 = .669 \\
 & \quad (1.7) \quad (1.3) \quad (1.2)
 \end{aligned}$$

In equations (6) and (8) the concentration coefficient is barely significant at the 10 per cent level in a one-tail test; in equation (7) it is clearly not significant. Deletion of the concentration variable from equations (6) and (8) causes reductions in the amount of variance explained of 1.1 and 1.6 percentage points respectively—increments significant only at the 20 per cent level in *F*-ratio tests.

To determine whether the regression relationship between intensity of technical employment and concentration was consistent within individual technology classes, separate linear regressions (omitting product characteristic dummy variables) were computed for the classes on which a reasonably large number of observations was available. For the 25 industries classified in the traditional product technology category, the fitted equations were:

$$(9) \quad \frac{E_i + S_i}{N_i} = 1.20 + .176C_i; \quad r^2 = .223. \\
 \quad \quad \quad (2.17) \quad (.063)$$

$$(10) \quad \frac{S_i}{N_i} = -.18 + .079C_i; \quad r^2 = .134. \\
 \quad \quad \quad (1.33) \quad (.042)$$

For the 24 industries classified as having general and mechanical product technologies, the following estimates resulted:

$$(11) \quad \frac{E_i + S_i}{N_i} = 13.36 + .291C_i; \quad r^2 = .091. \\
 \quad \quad \quad (8.68) \quad (.197)$$

$$(12) \quad \frac{S_i}{N_i} = .71 + .070C_i; \quad r^2 = .091. \\
 \quad \quad \quad (2.07) \quad (.047)$$

In all four cases the concentration coefficients are positive. All pass statistical significance tests at the 10 per cent level or higher, with the traditional group showing a somewhat more consistent tendency for the intensity of technical employment to increase with concentration.⁴

⁴ For the $(E_i + S_i)/N_i$ regressions, a test of the hypothesis that the traditional class intercept is greater than or equal to the G&M class intercept was rejected at the 10 per cent level, but a similar hypothesis regarding the slopes can be rejected only at the 35 per cent level. This lends support for regression model (2), which assumes different intercepts but equal slopes, over model (1), which assumes identical (zero) intercepts but unequal slopes. For the S_i/N_i regressions, there is no indication of significant differences in either the slopes or intercepts.

Simple linear regressions for industries in the chemical technology class revealed a *negative* correlation between both $(E_i + S_i)/N_i$ and S_i/N_i and concentration. However, the regression coefficients had *t*-ratios of only .61 and 1.24 respectively, and only five observations were involved.

III. *Interpretation*

We find then divergent results. Using one specification of the model, Schumpeter's hypothesis is sustained with flying colors. Using the alternative and theoretically preferred specification, the support is weaker but not entirely absent. Differences in the role of the dummy variables, and especially the technology class dummies, underlie this divergence. Still one important result is common to both models. When the dummy variables are introduced, the incremental explanatory power of concentration falls sharply.

Further analysis shows that the technology class dummies compete with concentration for explanatory power because they are positively correlated. The technically vigorous electrical and chemical groups had average and minimum concentration indices well above the full sample means. Average concentration in the electrical subsample (with only two observations) was 58, with a minimum value of 48. For the five chemical observations the average was 44, with a minimum of 31. The G&M group had an average *C_i* index of 41, with a range of from 18 to 70. In distinct contrast, the least progressive traditional class had an average of 29, with a minimum of 10 and only one observation (tobacco products) exceeding 50. Two alternative causal chains are compatible with this interdependence. The electrical and chemical classes might be more progressive on the average because they are more concentrated, or they may be more concentrated because in the past they have been more progressive.

Neither possibility can be rejected conclusively. It is clear, however, that the greater apparent progressiveness of the chemical and electrical groups is not due solely to higher concentration, for science has obviously been exceptionally generous to these groups during the past century. More support can be mustered for the contention that technological innovation associated with opportunity has led to concentration.⁵ The high concentration of market power in such fields as synthetic fibers, plastics materials, electric lamps, telephone equipment, and computing equipment was built at least partly upon patent and know-how barriers to entry and (in an earlier era) restrictive patent cross-licensing agreements. The successful exploitation of favorable opportunities may also have permitted especially rapid market share growth for innovating firms, contributing to above-average concentration. On the other hand, the undramatic pace of technological advance in such product areas as sawmill products, furniture, bakery products, shoes, and canned vegetables afforded little opportunity for the erection of strong patent and know-how entry barriers. It seems reasonable to conclude tentatively that the electrical and chemical technology class dummy variables have not captured explanatory power more appropriately attributable causally to concentration, although the possibility of a reverse flow from past opportunity to present concentration cannot be excluded.

Once interindustry opportunity differences are taken into account, the tendency for technical employment to increase with concentration is most persistent for the traditional industries, which are least concentrated on the

⁵ See also Almarin Phillips' analysis [3], which stresses this possibility.

average. This suggests a possible threshold effect: increases in concentration are conducive to technical vigor only in relatively atomistic industries, becoming an unimportant stimulus once a certain broad threshold is crossed [2]. To explore this possibility, an additional variable C_1^2 was introduced into regressions otherwise identical to equations (9) through (12). This test for nonlinearities yielded modest support for the hypothesis. In all four regressions, a relationship concave to the concentration axis was found, although only in the nonlinear analogue of equation (9) was the squared term's (negative) coefficient significant at the 5 per cent level. In all four cases technological employment per 1,000 employees reached a predicted maximum at concentration levels between 50 and 55 per cent—values exceeded only by the tobacco products industry in the traditional class, but by five to eight industries in the G&M class. The four regression equations predicted a zero ratio of technical to total employment at concentration levels between 10 and 14 per cent, suggesting that the threshold lies somewhere above this low range.

These results appear consistent with the neo-Schumpeterian hypothesis that oligopolists display a special affinity toward nonprice competition. Some degree of concentration is required before firms eschew price-cutting and grapple for market position through more complex innovative strategies. But in industries with high concentration—e.g., when the four-firm ratio exceeds 55 per cent—pricing interdependence is fully recognized, and group discipline may even be sufficiently strong to permit a “live and let live” attitude toward technological innovation.

IV. Conclusion

Three tentative conclusions emerge. First, the relationship between industrial inventive and innovative effort and concentration is a complex one, since high concentration and rich technological opportunity tend to coincide. Naïve tests of the Schumpeterian market power hypotheses are not apt to add much to our understanding. Second, even after interindustry differences in technological opportunity are taken into account crudely, there remains evidence of a modest positive correlation between the employment of scientists and engineers and concentration. This correlation is stronger than the results of my 1965 analysis suggested—undoubtedly because industries with traditional product technologies were deliberately excluded from the sample. And third, technological vigor appears to increase with concentration mainly at relatively low levels of concentration. When the four-firm concentration ratio exceeds 50 or 55 per cent, additional market power is probably not conducive to more vigorous technological efforts and may be downright stultifying.

A Graphical Proof of a Property of a Closed Linear Model of Production

The following are two well-known and related properties of a sufficiently well-behaved closed linear model of production: (1) All efficient infinite sequences of accumulation of capital goods converge to a balanced growth sequence. (2) The efficiency frontiers tend to "flatten out" as time goes on. For special models, the literature contains graphical proofs (or proofs using very simple mathematics) of the first property (see, for example, [3]) but not of the second. The purpose of this note is to present a graphical proof of (2) for a quite well-behaved model.

The two assumptions of the model that I shall use directly are the assumption of constant returns to scale and the assumption that the convex combination of two production processes is a production process. I shall not discuss here the more general set of assumptions underlying a strictly convex closed linear model of production [2].

A quite well-behaved closed linear model of production like that in [3] has the following implications.¹ With stocks of capital goods represented by point a in Figure 1, the state of technology allows the economy to reach, after engaging in productive activity, any point on or below the transformation curve AA' . That is, with point a as the starting point at time 0, AA' is the upper boundary of the set of points that can be achieved at time 1. Assume that there is no consumption, and so the points of AA' are

¹ The assumption on input intensities essential in [3] is not, however, essential in the present paper.

FIGURE 1

available for use as input points at time 1. AA' is the efficiency frontier, F_1 , at time 1.

Using the stocks of commodities represented by points in AA' , the economy can reach at time 2 any point on or below the efficiency frontier F_2 . Any point on or below BB' might, for example, be reached from point b , any point on or below CC' from point c , etc. F_2 is the envelope of curves like BB' and CC' . F_3 , F_4 etc. are similarly constructed.

There is a unique maximal balanced growth path—a unique von Neumann ray—such as v in Figure 1. (I assume that v is not one of the axes.) Let λ be the unique von Neumann growth factor. Growth along the von Neumann ray is known to be always efficient. That is, if the initial endowment is, like point c in Figure 2, a point in v , then λc is in F_1 , $\lambda^2 c$ is in F_2 , and so on. There are constant returns to scale, so that $\lambda c \lambda c'$ is associated with λc just as CC' is associated with c ; and any point such as d in $\lambda c \lambda c'$ in Figure 1 is λ times the point in CC' that lies on the same ray from the origin.

In models with efficiency frontiers shaped like those in Figure 1, each point on F_2 is reached by a unique path from a . For it can be shown that a single point in F_2 cannot be reached from two distinct points in F_1 . For example, suppose that the point λc could be reached from both point b

FIGURE 2

and point c . Then, because the convex combination of two production processes is a production process, point λc could also be reached from point e , a point on the line segment connecting b and c . And, because there are constant returns to scale, a point on v that is further from the origin than λc is could be reached from point e' . Because this result would contradict the fact that λc is on the efficiency frontier F_2 , our supposition that λc could be reached from both b and c must have been wrong.

In a model as well behaved as that in [3], it is not only true that a single point in F_2 can be reached from only a single point in F_1 ; but it is also true that two distinct points in F_2 cannot be reached from a single point in F_1 . In other words, curves like BB' and CC' each contribute only one point to the efficiency frontier F_2 . This is an important property as far as the following demonstration is concerned.

In Figure 2, the economy's initial endowment of stocks of capital goods happens to be in the unique von Neumann ray. In this special case, it is very easy to show that the efficiency frontiers tend to flatten out as time goes on. Starting at point c , the economy can reach any point in CC' in one time-period, any point in F_2 in two time-periods, any point in F_3 in three time-periods, etc. But starting at point λc , a point in CC' , the economy can reach, in one period, any point in $\lambda C\lambda C'$ and, in two time-periods, any point in λF_2 . At least one point of $\lambda C\lambda C'$, viz, the point $\lambda^2 c$ is in F_2 ; and at least one point of λF_2 , viz, the point $\lambda^3 c$, is in F_3 . Assume that the model is sufficiently well behaved that $\lambda^2 c$ is the only point of $\lambda C\lambda C'$ that is in F_2 , and $\lambda^3 c$ is the only point of F_2 that is in F_3 . Then it follows that, multiplying each point in F_t by $\lambda^{(1-t)}$, we get a situation like that depicted

FIGURE 3

in Figure 3. $\lambda^{-1}F_2$ must lie on or above CC' and contain only the point λc of CC' , because F_2 lies on or above $\lambda C\lambda C'$ and contains only the point $\lambda^2 c$ of $\lambda C\lambda C'$. $\lambda^{-2}F_3$ must lie on or above $\lambda^{-1}F_2$ and contain only the point λc of $\lambda^{-1}F_2$, because F_3 lies on or above λF_2 and contains only the point $\lambda^3 c$ of λF_2 , and so on. Thus, it is evident that, as time goes on, the efficiency frontiers tend to flatten out.

It can, in fact, be shown that the curve $\lambda^{(1-t)}F_t$ approaches the straight line F^* as t approaches infinity. Take any ray, such as r in Figure 3, that is not the von Neumann ray. Let a^* be the point at which r intersects F^* , and let a_t be the point at which r intersects $\lambda^{(1-t)}F_t$. The distance between a_t and a^* decreases monotonically as t increases. We know that the sequence of points a_1, a_2, \dots cannot include a point that has coordinates greater than those of a^* (i.e., a_t cannot be further than a^* is from the origin); because we know that $\lambda^{(1-t)}F_t$ cannot be convex to the origin. Therefore, we know that the distance between a_t and a^* converges to zero as t approaches infinity. Because the ray r was chosen arbitrarily, this convergence implies that, as t approaches infinity, the maximum distance between a point in F^* and a point in $\lambda^{(1-t)}F_t$ that lies on the same ray from the origin approaches zero; and so, as t approaches infinity, $\lambda^{(1-t)}F_t$ approaches the straight line F^* .

This, of course, shows only the flattening out of efficiency frontiers in

the special case in which the economy's initial endowment happens to lie in the von Neumann ray. Refer, then, to the situation shown in Figure 1; and suppose that the economy ignores all but one of the opportunities represented by points in AA' and chooses to reach only point c , which is in the von Neumann ray. Then, imagining that c is really the economy's initial endowment, we can construct pseudo efficiency frontiers, CC' , \bar{F}_2 , \bar{F}_3 , etc. \bar{F}_t approaches a straight line as t approaches infinity. It is not in general true that \bar{F}_{t-1} is tangent to F_t at $\lambda^{t-1}c$, unless the initial endowment happens to be in v . But property (1) can be shown to imply that, if t is very large and v intersects F_{t-1} at the point c' , $\lambda c'$ is below but arbitrarily close to F_t and \bar{F}_{t-1} is "almost" tangent to F_t at $\lambda c'$. The limiting \bar{F}_t has been shown to be a straight line. Thus, property (2) holds for this very well-behaved closed linear model of production.

Without loss of generality, it might be assumed that \bar{F}_{t-1} becomes almost tangent to F_t at time 2. Then Figure 1 would illustrate the eventual flattening out of efficiency frontiers.

A Paradox on Profits and Factor Prices*

When entry of foreign agricultural workers into the United States was curtailed, most individuals, and perhaps economists, indicated that agricultural wage rates would rise, and farm profits fall. However, in 1965 both wages and profits in the farm sectors most affected by the bracero cutback increased [7, pp. 1, 14]. Is the similar movement of the wage rate and profits coincidental, or does a paradox exist: profits may increase if entrepreneurs can convince labor to demand a higher wage? An examination of several price theory texts failed to substantiate the paradox. The purpose of this note is to prove that an increase in the price of a factor of production may

* After this note was written and accepted for publication, Nelson's article [3] was brought to my attention. This note is independent of Nelson's work and more general. Nelson also shows that an increase in the price of a factor of production may increase short-run profits (rents). However, while we state the necessary condition for the occurrence of the paradox irrespective of the number of variable factors, Nelson assumes that there is but a single variable factor, and his necessary condition is correct only when his restrictive assumption holds. Cf. footnote 6.

FIGURE 1

increase short-run profits in a competitive industry.¹ A rise in factor prices lowers equilibrium output but increases profits per unit. The net effect on total profits is likely to be positive sufficiently often so as not to reduce the paradox to a mere *curiosum*.

I

In this section we present a diagrammatic proof of the paradox. For simplicity, assume that there is only one variable factor, labor. Given this assumption, an increase in the wage rate leads to an equal percentage increase in marginal costs. In Figure 1, say, a 25 per cent increase in the wage rate shifts short-run industry marginal costs, MC , vertically by 25 per cent to MC' . The percentage increase in average variable costs of

¹ Of course, long-run profits in a competitive industry always equal zero, provided factor prices reflect properly capitalized rents.

any output also equals the percentage increase in wages. Since marginal costs are larger than average variable costs at equilibrium, an equal percentage increase in both means that the marginal cost-average variable cost spread, henceforth called simply the "differential," widens. At equilibrium, price equals marginal costs, and profits can be written as the product of output times the differential, minus fixed costs. If demand were inelastic at x^0 , it is clear that profits must increase, since output is constant, and the differential widens. BA is less than DC . Though output will usually decline, total profits still may increase because profits per unit increase. The necessary conditions are presented in the following mathematical section, where we also drop the single factor assumption.

Higher input prices always reduce monopoly profits. In monopoly, equilibrium output equals the industry profit-maximizing output. Total costs of any given output are larger after the input price rises, and the industry profit-maximizing output falls as the cost curves shift up. If the new, reduced equilibrium output, x_2^M , had been the output prior to the increase in wages, profits at the original wage rate would have been larger. But at original factor prices, profits at x_2^M were smaller than profits at the initial equilibrium output, x_1^M , where marginal revenue equals marginal cost. Consequently, profits must be less at x_2^M than at x_1^M .

In the competitive model, however, the penultimate sentence is false. Precisely because it is false, it does not follow that higher wages will decrease profits in a competitive industry. At the original wage rate, industry profits at x_2^C , the new competitive equilibrium output, would have been larger than profits at x_1^C , since marginal revenue is less than marginal cost between x_2^C and x_1^C . It is impossible to state a priori if profits in a competitive industry will rise or fall as factor prices change.²

II

As a matter of definition, industry profits equal total revenue minus total costs. Algebraically,

$$(1) \quad \Pi = Px - C(x, w_i),$$

where Π equals profits; P , price; x , industry output; $C(x, w_i)$, the total cost function; w_i , the price of the i th factor of production. Factor prices are parameters to the industry. Assume an increase in w_i . Prices of factors other than the i th remain fixed throughout the analysis and, as such, enter the cost function as parameters. Differentiation of (1) to determine the change in profits with respect to w_i gives³

$$(2) \quad \frac{d\Pi}{dw_i} = \frac{x\partial P}{\partial w_i} + \frac{P\partial x}{\partial w_i} - C_x \frac{\partial x}{\partial w_i} - C_i.$$

An increase in the factor price raises profits when (2) is positive.

² Higher factor prices to only one firm will reduce its profits, since a single competitor is like a monopolist in the sense that production is where marginal cost equals marginal revenue.

³ Notationally, $C_i = \partial C(x, w_i) / \partial w_i$; $C_x = \partial C(x, w_i) / \partial x$.

In order to evaluate (2), we first determine the change in equilibrium price and output. Equality of supply and demand price is the market equilibrium condition in a competitive industry.

$$(3) \quad P = D(x) = S(x, w_i),$$

where $D(x)$ is the demand relation, and $S(x, w_i)$ is the supply relation. One could solve for equilibrium output and price explicitly in terms of factor price. To calculate the change in equilibrium price and output with respect to an increase in w_i , $\partial P/\partial w_i$ and $\partial x/\partial w_i$, respectively, we differentiate (3),

$$(4) \quad \frac{\partial P}{\partial w_i} = D' \frac{\partial x}{\partial w_i} = S_i + S_x \frac{\partial x}{\partial w_i}.$$

The values of the derivatives, as well as the values of price and output in (1) and (2), are determined at the equilibrium point that satisfies (3). Transposing terms, one gets

$$(5) \quad \begin{aligned} \frac{\partial x}{\partial w_i} &= \frac{S_i}{D' - S_x}, \\ \frac{\partial P}{\partial w_i} &= \frac{D'S_i}{D' - S_x}. \end{aligned}$$

S_i , the change in supply price with respect to a change in the factor price, output being held constant, is positive. Assuming "normally" sloped demand and supply curves, the changes in equilibrium output and price are negative and positive respectively, as anticipated.

Two well-known conditions of production theory are noted without proof. First, a necessary condition for minimization of costs for any given output is the equality of marginal costs and the factor price-marginal physical product ratios of all n variable factors [5, pp. 65-66]. Assuming profit-maximizing competitors, marginal costs are equal to supply price.⁴ Therefore,

$$(6) \quad S(x, w_i) = C_x = \frac{w_i}{\Phi_i}, \quad (i = 1, \dots, n)$$

where $x = \Phi(v_1, \dots, v_n)$ is the production function, and Φ_i is the marginal physical product of the i th factor. Second, the first-order change in total costs with respect to a higher factor price, output being held constant, is proportional to the quantity of the factor [5, p. 68].

$$(7) \quad C_i = v_i, \quad (i = 1, \dots, n)$$

⁴ Strictly speaking, marginal costs equal supply only when the former are rising and greater than average variable costs. It is assumed throughout that all second-order conditions are fulfilled, and that no external economies exist.

Differentiating (6) with respect to w_i , noting that price equals marginal cost at equilibrium, and substituting (5) and (7) in (2), one gets⁵

$$(8) \quad \frac{d\Pi}{dw_i} = \frac{Px}{w_i} \cdot \frac{D'}{D' - S_x} - v_i.$$

As it stands, it is difficult to estimate the sign of (8) since the right-hand side contains absolute numbers, as opposed to ratios. Therefore, dividing numerator and denominator of the first term by $S_x D'$, and letting the share of v_i (that is, $w_i v_i / Px$) equal β ,

$$(9) \quad \frac{d\Pi}{dw_i} = v_i \left\{ \frac{\eta_s}{\beta(\eta_s - \eta_D)} - 1 \right\},$$

where η_D and η_s are the price elasticities of demand and supply respectively taken with their appropriate algebraic sign. Of course, v_i is positive, so profits increase when the expression in brackets is positive. Rearranging terms shows that it is positive when the absolute value of the ratio of demand elasticity to supply elasticity is less than the ratio of the share of all other productive factors to the share of the higher-priced factor. Mathematically, the necessary condition is⁶

$$(10) \quad \left| \frac{\eta_D}{\eta_s} \right| < \frac{1 - \beta}{\beta}.$$

Either a perfectly inelastic demand or perfectly elastic supply is a sufficient, though not necessary, condition for a higher factor price to result in larger profits. Differentiating equation (9) would show that, *ceteris paribus*, it is more likely that profits will increase (1) the smaller the share of the higher-priced input, (2) the more inelastic is demand, or (3) the more elastic is supply. It is interesting that profits may increase even if demand is elastic, in which case total revenue decreases as input and equilibrium output prices increase.

Though a unit tax like higher factor prices shifts supply upward, a tax generally will lower profits. The profit and market equilibrium equations respectively are

$$(1') \quad \Pi = Px - C(x) - tx,$$

$$(3') \quad P = D(x) = S(x) + t,$$

⁵ From (6), $S_i = 1/\Phi_i = C_x/w_i$, and at equilibrium $C_x = P$.

⁶ Using our notation, Nelson states that an increase in the price of a factor will raise profits when $|\eta_D/\eta_s| < \eta_{AVC}$ [3, p. 391]. We have $(1-\beta)/\beta$ on the right-hand side of the inequality. When there is only one variable factor, the case considered by Nelson, the two inequalities are identical as η_{AVC} equals $(1-\beta)/\beta$. In the single variable factor case, $v_i w_i/x = AVC$ and $\eta_{AVC} = (x w_i dv_i/dx - v_i w_i)/v_i w_i$. At equilibrium, $P = w_i dv_i/dx$, and $\eta_{AVC} = (xP - v_i w_i)/v_i w_i = (1-\beta)/\beta$. However, in the general case of several variable factors, Nelson's inequality is incorrect. In general, whether profits will increase depends upon the share of the higher-priced factor, and not the elasticity of average variable costs.

where t equals the unit tax. Performing calculations similar to (2)–(8), one gets

$$(9') \quad \frac{d\Pi}{dt} = x \left\{ \frac{\eta_D}{\eta_S - \eta_D} \right\}.$$

If demand and supply are negatively and positively sloped respectively, (9') cannot be positive. Profits remain unchanged when a unit tax is levied only if demand is perfectly inelastic, or supply is perfectly elastic.

The difference between higher factor prices and a unit tax lies in that the tax does not change the differential, while higher input prices increase the differential. For example, in Figure 1, higher wages shift MC and AVC vertically by the same percentage and, consequently, the differential widens. A unit tax, however, raises MC and AVC by the amount of the tax. MC and AVC are vertically displaced by the same absolute, not percentage, amount. Since the differential remains constant, and output usually declines, a tax tends to reduce profits.

III

How often will a rise in the price of a factor increase profits? It appears that (10) will be satisfied relatively frequently. For example, if the ratio of demand elasticity to supply elasticity equals one, profits increase provided the share of the higher-priced factor is less than one-half. Profits generally will increase when the share of the factor is small. If the factor's share is ten per cent, profits increase provided the ratio of demand to supply elasticities is less than nine, a condition which casual empiricism suggests will usually hold. Though a change in the price of only one factor has been assumed, it should be clear that higher prices for several factors do not preclude enlarged profits.

While it is not our purpose to explain recent changes in agricultural profits in terms of the wage rate, nor even to suggest that the simplistic competitive model is entirely appropriate, the values for factor shares and elasticities of supply and demand are such that within the competitive model a higher wage rate would enlarge agricultural profits. In view of the numerous statistical estimates of factor shares and price elasticities, one feels rather uneasy about giving a single, point estimate. Nevertheless, labor's share in agriculture is taken to be 65 per cent [2, p. 215]. Braceros were employed primarily in the production of fruits and vegetables. The elasticity of demand for fruit and tree nuts has been estimated to be -0.36 , and the elasticity of demand for vegetables is estimated at -0.10 [1, p. 59]. It follows from (10) that profits in the fruit and tree nuts and vegetables "industries" would increase if the elasticities of supply were no less than 0.70 and 0.20 respectively. Though statistical estimates of supply are somewhat less numerous and more unreliable, estimates of short-run supply elasticities of other farm products are often between 0.50 and 1.0 [4] [6, pp. 94–105]. Therefore, profits in the vegetable industry should increase, and perhaps in the fruit and tree nuts industry as well. To repeat, we provide the example only because agriculture is considered to be the com-

petitive industry par excellence, and not because demand shifts and other exogenous changes are unimportant in explaining farm profits.

A corollary of the paradox is that profits no longer are a good signalling device. Assume that an industry is initially in long-run equilibrium. Since the analysis of higher factor prices was a short-run analysis, the number of firms and quantity of capital in an industry were assumed constant. Larger absolute profits, therefore, mean a higher rate of return, which would induce entrants. However, assuming the relative increase in factor prices is permanent, the long-run supply curve shifts upward, and equilibrium output of the industry falls. If firms' isoquants are homothetic with respect to their origins, a higher price for a factor does not change the optimum firm size. Higher factor prices increase long-run average costs but do not change the output at which average costs of a firm are minimized. Consequently, the reduction in industry output must be accommodated in the long run by the exit of firms from the industry. When the paradox holds, entry is encouraged though the number of firms in an industry is already larger than the industry can support in the long run.

Friedman-Meiselman and Autonomous Expenditures

Milton Friedman and David Meiselman in a now famous paper [2] have sought to demonstrate the "superiority" of the quantity theory over the autonomous expenditures theory by testing simplified versions of these theories with U.S. data over the period 1897-1958. Their study has attracted widespread criticisms and comments centered in particular on the simplicity of the models used, the periods covered in the tests, and their definition of autonomous expenditures [1][3]. This note does not seek to

question the meaning of the results obtained by Friedman and Meiselman (FM), nor is it an attempt to evaluate the criticisms raised by participants in the debate. Rather, it has the limited objective of demonstrating that FM have not consistently applied their own criteria when selecting the variables of the autonomous expenditures model. It is also shown that a correct application of their criteria for selection provides support for the definitions they used.

FM's version of the autonomous expenditures theory is essentially an expansion of Keynes's fundamental equations. They define an income concept, Y , equal to the sum of all expenditures induced by income, U , and autonomous expenditures of all kinds, A^* . Autonomous expenditures are defined in the usual manner as being independent of current income flows while induced expenditures are a function of Y , giving the following model:

$$Y \equiv U + A^*$$

$$U = f(Y)$$

and also

$$U = g(A^*).$$

This leaves FM with the empirical specification of the variables U and A^* , for in this form the model can accommodate different empirical judgments. They attempt to provide an objective foundation for the selection of autonomous and induced expenditures by performing tests designed to determine the substitutability of individual items with an initial tentative grouping of autonomous and induced items.

The rationale of these tests together with an example of their application in a specific case has been outlined by FM elsewhere [1] [2] and need not be reiterated here. The following is a general formulation of their criteria. Total income, Y , is divided into three parts: (1) a doubtful item, D , which it is desired to classify as an autonomous or induced item; (2) autonomous expenditures, A , which *exclude* the doubtful item; and (3) induced expenditures, N , which also *exclude* D . If, as a result of the tests, D is classified as a component of autonomous expenditures, autonomous expenditures will be $D+A$ for the purposes of the model. Hence the question is whether $D+A$ or A alone is the preferable definition of autonomous expenditures. FM argue that if D and A were perfect substitutes as income-generating expenditures, then N would tend to have a higher correlation with $D+A$ than with either D or A alone. This is the first test. As the sum of autonomous expenditures, induced expenditures, and the item in doubt equals income, the test can be performed in reverse to determine whether or not D is a perfect substitute for N .¹ This is the second test, and so the two tests are:

¹ The additive property of N , D , and A is such to permit the second test to be carried out. This possibility did not arise for the tests performed by FM to determine the definition of money. (For a description of these tests see [2, pp. 242-46].) It is for this reason that the tests for autonomous expenditures and for money differ in execution, even though the idea underlying them is the same.

(i) Autonomous test

(ii) Induced test

$${}^rN(D + A) > \begin{bmatrix} {}^rND \\ \text{and} \\ {}^rNA \end{bmatrix} \qquad {}^rA(D + N) > \begin{bmatrix} {}^rAD \\ \text{and} \\ {}^rAN \end{bmatrix}$$

FM tentatively define autonomous expenditures to comprise net private domestic investment, the government deficit on income and product account, and the net foreign balance. Consumers' expenditure on durable and nondurable goods is tentatively defined as induced expenditures. When making the tests, FM separate out various items in turn for treatment as the doubtful item. The items considered by FM in the tests are consumer durables, imports, exports, the net foreign balance, taxes, and the government deficit. The results of these calculations, although in many cases ambiguous, provide the basis for the choice of autonomous and induced expenditures.

As mentioned previously, FM have been criticized on the grounds that their definition of autonomous expenditures misrepresents the autonomous expenditures model. We cannot be sure that FM's criteria identify autonomous expenditures. At best, the tests they conduct only show that D and A are substitutes as income-generating expenditures, not that these items are independent of current income flows.² FM concede that the concept of autonomous expenditures they selected may have been unfavorable to the autonomous expenditures theory, but contend that it had the merit of being "... derived by a specifiable and reproducible procedure ..." [1, p. 784]. FM's defense is unnecessarily weakened by an inconsistent application of their own criteria. In particular, they (1) do not always perform *both* relevant tests, (2) fail to use a consistent concept of income and autonomous expenditures, and (3) make tests which do not follow from their criteria.

Both tests are required by FM to classify an item as an autonomous or induced expenditure. The doubtful item, D , would be included as a component of autonomous expenditures if test (i) were satisfied, and test (ii) not satisfied. It would be considered induced if these results were reversed. If neither of these combinations holds, then the results must be considered ambiguous. Despite their own requirement that both tests be carried out, FM do not perform test (ii) in four cases. This omission will be corrected in the tests considered below.

The second criticism stems from FM's uncertainty whether Y should be defined as personal disposable income or personal disposable income plus the undistributed income of corporations and the excess of wage accruals over wage payments. These latter items were deducted from the tentative grouping of autonomous expenditures in some of their tests. This change of definition generates confusion, and in at least one instance (discussed below) has a bearing on the results of the tests.

² In order to avoid the least-squares bias which may result from including induced items in A^* , Ando and Modigliani [1, p. 787] have specified that an autonomous variable "... should be uncorrelated with the error term of the test equation"; although FM consider this to be "... figurative rather than operational" [1, p. 784]. Further discussion of this problem is beyond the scope of this paper.

The last criticism can be illustrated by considering FM's tests for the treatment of imports, exports, and the net foreign balance. FM use the following symbols in these tests:

- C = personal consumption expenditures,
 D_0 = net private domestic investment plus the government deficit on income and product account,
 E = exports,
 M = imports,
 $F = E - M$ = net foreign balance.

FM first consider imports, assuming in terms of their tentative definition of autonomous expenditures that exports are autonomous. According to our interpretation of FM's criteria for allocating items between the categories U and A^* , we have the following classification:

$D = M$ (doubtful item)

$N = C$ (induced expenditures, excluding doubtful item)

$A = D_0 + E$ (autonomous expenditures, excluding doubtful item)

Hence the two tests should be:

(i) Autonomous test

(ii) Induced test

$${}^rC(D_0 + F) > \begin{cases} {}^rC \cdot M \\ \text{and} \\ {}^rC(D_0 + E) \end{cases} \quad {}^r(C - M)(D_0 + E) > \begin{cases} {}^rM(D_0 + E) \\ \text{and} \\ {}^rC(D_0 + E) \end{cases}$$

The present writer performed these tests and the results are set out in Table 1. The time periods used conform to those used by FM, and the data were derived from the source given in their Appendix Table II-B2. One of the time periods selected by FM, 1940-1952, includes war years, and may give unreliable results. An extra column has been included in Table 1 to give results for the period 1929-1952, excluding the war years (1942-1946). It can be seen that the exclusion of the war years from the period dramatically improves the correlations; but it gives the same results for the tests. Calculations similar to those in Table 1 were performed including a more recent period (1953-1964) and using revised data published in *Survey of Current Business* (August 1965), but the results do not differ substantially and are not reported here. In addition, a comparison between the results shown in Table 1 and those obtained by FM is given in Table 2.

FM carry out test (i), and the inequality is not satisfied. On the basis of this result they suggest that M should be regarded as induced. This test was performed incorrectly: for induced expenditures excluding the doubtful item, they used $C - M$ rather than C .³ The amended calculations are not

³ The use of $C - M$ rather than C for induced expenditures excluding M could be defended on the grounds that induced expenditures, C , already include a part of M , namely imported consumer goods. Hence $C - M$ may be a better approximation to induced expenditures than C when M is being considered for inclusion as an autonomous item. However, the tests adopted by FM assume in effect that the item being tested is either entirely autonomous or entirely induced, and they do not permit the classification of the doubtful item as partly autonomous and

substantially different. But FM did not apply test (ii), in order to confirm that *M* is induced. From the figures in Table 1, it can be seen that none of the correlations supports the conclusion that *M* is an induced item.

FM proceed to consider exports, on the assumption that *M* is induced. The autonomous test was undertaken and FM reject the hypothesis that *E* is autonomous, concluding that *E* is "mixed." This test was logically correct, but because of the definition of income adopted (see explanation above) their results differ from those reported here. The results given in Table 1 are more favorable than FM's towards considering *E* an autonomous item: correlations for two periods satisfy test (i), and the induced test is not satisfied.

The relatively low correlations between *E* and *D*₀ in test (ii) are not inconsistent with *E* being an autonomous item. Using the general formulation given earlier, *A* should be more highly correlated with (*D*+*N*) than with either *D* alone or *N* alone if *D* and *N* are induced. However, this inequality

partly induced [2, p. 185 n. 2]. Furthermore, if FM had this in mind when using *C-M* rather than *C*, they should have used *C* rather than *C-M* for induced expenditures including *M* when performing the tests for exports (in which *M* is assumed to be induced).

^a Correlations for the period 1929–1952, excluding the war years, have not been included in the classification, so as to permit a comparison with FM's results.

^b The correlations for a period satisfy a test when, using the induced test as an example:

$$rA(D + N) > rAD \text{ and } rAN$$

A test is classified as being "not satisfied" when the inequality is reversed or where the correlation on the LHS exceeds one of those on the RHS but is less than the other (the latter result is classified as hybrid). Following FM, the sign of the correlation coefficient has been ignored when making the classification.

Sources: Table 1 and Appendix Table II-A3 to FM [2, p. 252].

may not be reversed even if D is autonomous. The correlation between A and D , the autonomous items, may well be the smallest of the three. This possibility has led to the classification adopted in Table 2.

Finally, FM conduct tests for F , the net foreign balance. In terms of the terminology adopted here, we have $D = F$, $N = C$, and $A = D_0$, so that the two tests should be:

$$\begin{array}{ll}
 \text{(i) Autonomous test} & \text{(ii) Induced test} \\
 rC(D_0 + F) > \begin{bmatrix} rC \cdot D_0 \\ \text{and} \\ rC \cdot F \end{bmatrix} & rD_0(C + F) > \begin{bmatrix} rC \cdot D_0 \\ \text{and} \\ rF \cdot D_0 \end{bmatrix}
 \end{array}$$

FM perform test (i), and decide that it is consistent with the foreign balance

being autonomous. Again they use $C-M$ rather than C for induced expenditures, which appears to be incorrect. The amended calculations given here support their conclusion. FM could have strengthened their case by performing test (ii). The results of this test are shown in Table 1 and they provide no evidence to contradict their conclusion. The low correlations between F and D_0 may be consistent with F being autonomous. FM appear to argue that their classification of F as an autonomous item is consistent with their results for exports and imports: for exports, classified a mixed item, can be considered as the sum of imports (induced) and the foreign balance (autonomous). However, the conclusion that the foreign balance is autonomous may also be consistent with exports being autonomous and imports a mixed item, the interpretations suggested by the calculations shown in Table 1.

As a further illustration of FM's failure to apply their own criteria correctly, their tests for taxes may be considered. In terms of the interpretation adopted here, $N=C$, $D=T''$ and $A=A^*+T''$, so that the tests for taxes (FM's T'' concept) should be:

| | |
|--|--|
| <p>(i) Autonomous test</p> $r_{C \cdot A^*} > \begin{cases} r_{C \cdot T''} \\ \text{and} \\ r_{C(A^* + T'')} \end{cases}$ | <p>(ii) Induced test</p> $r_{(C - T'')(A^* + T'')} > \begin{cases} r_{(A^* + T'')T''} \\ \text{and} \\ r_{C(A^* + T'')} \end{cases}$ |
|--|--|

These tests were carried out with annual data for the periods 1929-1945, 1946-1964, and 1929-1964 but the results are ambiguous, as were those obtained by FM.⁴

On the results of the tests with imports, exports, and the net foreign balance, FM decide to treat the net foreign balance as an autonomous item in the autonomous expenditures model used in the comparison with the quantity theory. Some critics have been surprised by FM's willingness to consider $(E-M)$ as a single item. The question of the appropriate multiplier for income determination is one of historical conjecture [4]. Samuelson [5, p. 149] has argued that "the cases in which the trade balance can be treated as an autonomous element are necessarily those in which—through the action of exchange control, exchange depreciation, or lender-borrower psychology—capital movements prove to be the bottleneck to which trade movements adjust themselves." In this context, it should be noted that

⁴ Correlations for 1929-1945 satisfied the autonomous test but the inequality was reversed in the other periods, and the induced test was not satisfied. FM performed the following tests with annual and quarterly data for the period 1946-1958 to determine the appropriate treatment of taxes, T'' (for the definition of T'' and a description of these tests see [2, pp. 253-56]).

- (i) Autonomous test
 $r_{(C-T'')(A^*+T'')} > r_{(C-T'')T''}$ and $r_{(C-T'')A^*}$
- (ii) Induced test
 $r_{C \cdot A^*} > r_{A^* \cdot T''}$ and $r_{(C-T'')A^*}$

The results of these tests were ambiguous, and FM decided to retain their tentative classification of the government deficit as an autonomous item.

correlations for two periods between the years 1929–1952 favor treating the foreign balance as an autonomous item.

This rationalization of the results obtained for the net foreign balance raises the question as to whether the same treatment of the net foreign balance is justified for the period not covered by these tests. Much of the impact of FM's study stemmed from the "superiority" of the quantity theory over the autonomous expenditures theory during the years 1897–1928.

International Short-Term Capital Movements: Comments

COMMENT I

The sensitivity of short-term international capital movements to the interest rate differentials between the leading financial centers is becoming increasingly important to policymakers as attempts are made to finance basic deficits in the balance of payments by retaining domestic and attracting foreign, private short-term capital. For this reason the possibility of upward bias in the estimates of sensitivity of short-term funds to the interest rate differential derived by Jerome L. Stein [9] deserves mention. Two aspects of Stein's article are of concern: (1) the distinction between and the test of the applicability of the stock and the flow theories, and the consequent rejection of the stock theory, and (2) the estimates of the sensitivity of capital movements to the rate differential.

1. The susceptibility to the rate differential of the stock of assets and liabilities or of the absolute rate of change of the stocks—the flow model—is important because, “if the interest differential determines a flow, a constant basic deficit is consistent with a constant interest differential” [9, p. 40], whereas if the “differential determines a stock . . . a constant or declining basic deficit requires a growing interest differential” [9, p. 40].

The estimating equation for the stock model is:

$$(15)^1 \quad S(t) = b_0 + b_1 S(t-1) + b_2 R(t) + b_3 x_3(t)$$

and for the flow model is:

$$(22) \quad y(t) = d_0 + d_1 R(t) + d_3 x_3(t)$$

where $S(t)$ is the stock of liabilities to foreigners or of U.S. assets in period t —the two concepts being analyzed separately; R is a speculative variable which does not concern us in this note; x_3 is the uncovered interest differential between London and New York, and $y(t)$ is equal to $S(t)$ minus $S(t-1)$.

Given these postulated relationships, the difference between the stock model and the flow model depends upon the value of b_1 . Either b_1 is significantly different from unity or it is not. If not, the two equations are identical and the stock and the flow theories merge into one. If b_1 is different from unity, the stock equation is a variant of a standard stock adjustment model in which the change in the stock in a period—the flow—is some proportion of the difference between the desired stock and the actual stock at the end of the preceding period: the desired stock being determined by $R(t)$ and $x_3(t)$. In the latter case, if $R(t)$ and $x_3(t)$ stay constant, the change in the stock will monotonically approach zero with the passage of time.² No set of observations yielded a value of b_1 significantly different from unity.

To compare the relative merits of the stock and flow hypotheses, the stock model is recast in terms of flows by taking a first difference of equation (15):

$$(38) \quad \Delta S = K_1 \Delta R - K_3 \Delta I \quad (\text{where } \Delta I = -x_3).$$

The test for the validity of the stock and flow theories is a multiple regression of the transfers of short-term capital in period t on the four independent variables, I , ΔI , R , ΔR . From equation (38) the stock theory is alleged to be the better theory if the first differences prove to be the significant explanatory variables, and from equation (22) the flow theory will be the more acceptable if the levels variables are statistically significant. Equation (38) does not include the first difference of the variable $S(t-1)$ on the grounds that the lagged flow was not a statistically significant explanatory variable of the flow in equations (33) or (37). This lack of significance of the lagged flow emphasizes the difficulties inherent in any attempt to establish the validity of either theory on purely empirical grounds. A linear relationship

¹ The numbers of the equations are those of the original article.

² From (15) and assuming $b_0 > 0$ and $b_1 < 1$,

$$(15A) \quad S(t) - S(t-1) = y(t) = b_0 + (b_1 - 1)S(t-1) + b_2 R(t) + b_3 x_3(t).$$

of $\Delta S(t)$ to $\Delta S(t-1)$ is not a necessary feature of a stock adjustment model when the desired stock is itself changing with each observation, but the lack of applicability of a linear relationship in the lagged flow variable must impugn the use of first difference variables as a satisfactory test for the stock theory—particularly so when the original formulation of both models was identical.³ The consequent rejection of the stock theory on the basis of the statistical insignificance of the two first difference variables in equations (39) and (41) does not constitute adequate proof of the superiority of the flow theory [9, pp. 63–64]. In fact the relationship between the flow or change in the stock and the interest differential is complex and the volume of capital movements may well be a function of both the level and the first difference. A larger differential may not attract a proportionate increase in capital, and the sensitivity to a differential may depend in turn on the levels of the interest rates if the average yield of the portfolio affects its distribution.

The rejection of the stock theory can also be questioned on theoretical grounds. A given interest rate differential offers an infinitely elastic demand curve for individual transfers of international capital. The corresponding supply curve is upward sloping denoting increased transfers to be potentially generated by larger differentials. If the flow theory is held, the supply curve is defined as a flow of capital per period; if the stock theory is held, the supply curve describes the reaction of a given stock of potentially internationally mobile capital which is extant at any one time: a change in the differential will induce a redistribution of the stock and, once the redistribution of the stock is finished, any further international transfers will comprise the international allocation of accretions to the global stock of international short-term capital. The flow theory contends that a given differential will generate capital transfers at a constant rate for an undefined length of time. The lack of any integral part of the theory which explains the termination of the process is an important weakness in the theory since, in its absence, the theory must allow for the existence of potentially infinite stocks of money. Additionally, the flow theory fails to explain why owners of internationally mobile capital should so regulate their total activities as to generate an approximately constant rate of transfers rather than responding quickly to the advantage inherent in the change in the differential and then letting the rate of transfers decrease—the latter behavior pattern being in accord with the stock adjustment model given in equation (15A).⁴

The rejection of the stock theory in favor of the flow theory is not warranted by the evidence.⁵

2. The other item of concern is the possibility that the estimates of the sensitivity of the flows of short-term capital are subject to an upward bias. Assuming no speculative influence, parity in the Treasury bill rates in London and New York is estimated to yield an inflow of foreign private

³ Given $b_1=1$.

⁴ See footnote 2 above.

⁵ This is particularly true, for example, in equation (39) where the levels variable, I , is not significantly different from zero and in fact, has a " t " value of less than that of ΔI .

capital into New York of \$850 million per annum⁶ and an outflow of U.S. capital of \$159 million per annum. The institution of a one per cent differential in favor of London yields an estimated inflow of \$665 million and an outflow of \$436 million per annum, and a reduction in the net inflow of \$462 million per annum. The possible upward bias has two sources. The first source is the multiplication by twelve of the monthly rate of flow in order to compute an annual rate of flow. This procedure is only consistent with the adoption of the flow theory and the constant rate of flow of capital in response to a given differential.

Secondly, the sensitivity of capital flows to an interest differential may be exaggerated if the differential changes its sign during the period. A change in sign would result in the same capital being counted as it moves in both directions as funds, originally attracted away from Europe by an increase in U.S. short-term interest rates, return to Europe as the U.S. rate declines relatively and are then switched back to the United States once more as the old differential is reestablished. In the same way, the estimates of response to an increase in the differential do not consider the problem of maintaining the new differential over a twelve-month period.

The possibility of the estimates of the sensitivity of short-term capital movements to the interest differential being biased upward hinges on the acceptance of a stock adjustment hypothesis according to which a change in the differential will result in a large proportion of the total flow being generated in the first period. The argument in this note is that the refutation of the stock adjustment theory is insufficient for the possibility of an upward bias in the estimates to be eliminated.

⁶ The interest variable is not significant for the computation of flows of private foreign capital but was used in measuring the induced flows in the summary estimate [9, p. 65].

COMMENT II

In a recent article in this *Review* [9], Stein reviews attempts by Bell [2] and Kenen [7] to use multiple regression techniques to estimate international short-term capital movements resulting from interest rate differentials. He correctly points out that certain of Bell's and Kenen's parameter estimates are biased and inconsistent. Stein then goes on to estimate the sensitivity of capital flows¹ to uncovered interest rate differentials and to a proxy variable which, he claims, reflects the effects of expectations about the future foreign-exchange rate. I suggest that under a more reasonable specification of Stein's system of equations, his method also yields biased and inconsistent estimates. I further question the interpretation of the proxy that Stein uses and suggest that, even if he could obtain a consistent estimate of the parameter of the proxy variable, he is unjustified in interpreting it as an estimate of the effects of speculation on capital movements.

¹ In fact, all equations below deal with stocks of assets rather than flows. As Stein points out, the analysis is basically the same whether one prefers to deal with stocks or with flows.

I. *The Stein Model*

Stein [9, p. 48] posits a supply of dollars $S(t)$ at time t :

$$(E.1) \quad S(t) = S(t-1) + T - c_1p - w.$$

That is, the supply of dollars in period t is equal to the supply of dollars at the end of the previous period ($S(t-1)$) plus dollar sales by foreign governments (T) minus the basic balance surplus of the United States, which is a function of the exchange rate (p) and a disturbance term (w). (E.1) and a demand equation for spot dollars and demand and supply equations for forward dollars yield the following reduced-form equations [9, p. 51]:

$$(E.2) \quad x_2 = A_1p^* - A_2[S(t-1) + T - w] + A_3x_3$$

$$(E.3) \quad p = B_1p^* + B_2[S(t-1) + T - w] - B_3x_3$$

where x_2 is the forward rate, p^* is the expected price of foreign exchange prevailing when the investor wants to repatriate his funds, and x_3 is the uncovered interest rate differential.

Stein then substitutes (E.3) into (E.1) and gets [9, pp. 52-53]:

$$(E.4) \quad S(t) = K_0 + K_3x_3 - K_1p^* + K_2S(t-1) + K_2(T - w).$$

But p^* (the expected price of foreign exchange when the speculator wants to repatriate his funds) is unobservable. In an attempt to solve this practical problem he goes to (E.2), regresses x_2 on x_3 , and derives the residual R . This residual, the difference between the actual and the predicted value of x_2 , will approach the value of $A_1p^* - A_2S(t-1) - A_2(T - w)$ as the sample size for the regression approaches infinity.² Next, Stein develops (E.5) from (E.4) and then estimates (E.7) by ordinary least squares:

$$(E.5) \quad S(t) = K_0 + K_3x_3 + K_2S(t-1) \\ + K_4R - K_4R - K_1p^* + K_2(T - w)$$

or

$$(E.6) \quad S(t) = K_0 + K_3x_3 + K_2S(t-1) \\ + K_4R - K_4A_1p^* + K_4A_2S(t-1) \\ + K_4A_2(T - w) - K_1p^* + K_2(T - w)$$

or

$$(E.7) \quad S(t) = K_0 + K_3x_3 + (K_4A_2 + K_2)S(t-1) \\ + K_4R + r$$

where

$$(E.8) \quad r = -(K_4A_1 + K_1)p^* + (K_4A_2 + K_2)(T - w).$$

² All work below will assume that R is based on an infinitely large sample.

Can one obtain a consistent estimate of K_4 in (E.7) by ordinary least squares? The answer depends on whether r is correlated with $R = A_1 p^* - A_2 S(t-1) - A_2(T-w)$. r will be uncorrelated with R if and only if both $(K_4 A_1 + K_1)$ and $(K_4 A_2 + K_2)$ are equal to zero, i.e., r is equal to zero.³ It turns out that there exists one value for K_4 ,

$$K_4 = - \frac{a_1(g_2 + h) + g_1 h}{g_1},$$

which satisfies $K_4 A_1 + K_1 = K_4 A_2 + K_2 = 0$.⁴ Even though it still has not been demonstrated that the coefficient of R in (E.7) necessarily takes on that specific value, let us assume that it does indeed do so.⁵

A moment's thought about (E.7), however, should make us very uneasy. If r is equal to zero, (E.7) is an *exact* equation. Why should relatively poor econometric fits of (E.7) result if (E.7) is asymptotically an exact equation? There are two possible alternatives: (1) the poor fit of (E.7) results from a poor estimate of A_3 in the regression of x_2 on x_3 ; or, (2) the model is misspecified and, therefore, empirical results do not reflect postulated theory.

II. An Alternative Model

Under a slightly different specification of the model it is easy to demonstrate that ordinary least squares will yield inconsistent estimates of the parameters of (E.7) unless one is willing to violate the restrictions on the parameters of the structural equations which Stein imposes. Let us attach error term u to Stein's equation (A3) [9, p. 49] to yield

$$(A3') \quad D(i) = h(x_3 - x_2) + a_1(p - p^*) + a_3 x_3 + u$$

and also attach an error term v to equation (9) [9, p. 50]:

$$(9') \quad g_1 p + (g_2 + h)x_2 = hx_3 + g_1 p^* + v.$$

³ This assumes that the covariance between p^* and $T-w$ is zero, a valid assumption if p^* and T are treated as predetermined variables.

⁴ $K_4 A_1 + K_1 = K_4 A_2 + K_2 = 0$ implies that

$$K_4 = - \frac{K_1}{A_1} = - \frac{K_2}{A_2}.$$

Since Stein [9, pp. 51-52, footnotes 11 and 12] presents the values of the parameters of the reduced form equations in terms of the parameters of the structural equations, K_4 can be expressed in terms of the structural parameters a_1, a_3, g_1, g_2 , and h :

$$K_4 = - \frac{K_1}{A_1} = - \frac{a_1(g_2 + h) + g_1 h}{g_1}$$

$$K_4 = - \frac{K_2}{A_2} = - \frac{a_1(g_2 + h) + g_1 h}{g_1}.$$

For an interpretation of these structural parameters, the reader should consult [9, pp. 48-51].

⁵ I have been unable to develop a rigorous proof of this although there are intuitive reasons to suspect that it is so. In any case, it is a moot question since the discussion below suggests that under a more reasonable specification of the system, Stein's method certainly yields inconsistent estimates.

Surely, Stein did not mean to assume an exact demand function for spot exchange or an exact function to describe net demand for forward exchange. Apparently, he assumed that attaching w to his equation (A1) [9, p. 48] would reflect all these disturbances without changing the nature of the model. That, however, is not true.

Using (A3') and (9') along with (E.1), we derive a new set of reduced form equations, (E.2') and (E.3'):

$$(E.2') \quad x_2 = A_1 p^* - A_2 [S(t-1) + T - w - u] + A_3 x_3 + A_4 v$$

$$(E.3') \quad p = B_1 p^* + B_2 [S(t-1) + T - w - u] - B_3 x_3 + B_4 v.^6$$

Substituting (E.3') into (E.1) yields:

$$(E.4') \quad S(t) = K_0 + K_3 x_3 - K_1 p^* + K_2 S(t-1) \\ + K_2 (T - w) + K_5 u + K_6 v.^7$$

Now, from (E.2'), regress x_2 on x_3 and calculate the residual, $R' = A_1 p^* - A_2 [S(t-1) + T - w - u] + A_4 v$.

Develop (E.5'):

$$(E.5') \quad S(t) = K_0 + K_3 x_3 + K_2 S(t-1) + K_4' R' \\ - K_4' R' - K_1 p^* + K_2 (T - w) + K_5 u + K_6 v$$

or

$$(E.6') \quad S(t) = K_0 + K_3 x_3 + K_2 S(t-1) + K_4' R' \\ - K_4' A_1 p^* + K_4' A_2 S(t-1) \\ + K_4' A_2 (T - w) - K_4' A_2 u - K_4' A_4 v \\ - K_1 p^* + K_2 (T - w) + K_5 u + K_6 v$$

or

$$(E.7') \quad S(t) = K_0 + K_3 x_3 + (K_2 + K_4' A_2) S(t-1) + K_4' R' + r'$$

where

$$(E.8') \quad r' = - (K_1 + K_4' A_1) p^* + (K_2 + K_4' A_2) (T - w) \\ + (K_5 - K_4' A_2) u + (K_6 - K_4' A_4) v.$$

R' will not be correlated with r' if and only if r' is equal to zero, i.e., if and only if $K_1 + K_4' A_1 = K_2 + K_4' A_2 = K_5 - K_4' A_2 = K_6 - K_4' A_4 = 0$. Therefore, K_4' must satisfy each of the following conditions:

$$^6 A_4 = \frac{a_1 + c_1}{J}; \quad B_4 = \frac{h}{J} \\ ^7 K_5 = 1 - K_2 = c_1 B_2; \quad K_6 = -c_1 B_4$$

$$K'_4 = -\frac{K_1}{A_1} = -\frac{a_1(g_2 + h) + g_1h}{g_1} < 0$$

$$K'_4 = -\frac{K_2}{A_2} = -\frac{a_1(g_2 + h) + g_1h}{g_1} < 0$$

$$K'_4 = \frac{K_5}{A_2} = \frac{c_1B_2}{A_2} = \frac{c_1(g_2 + h)}{g_1} > 0$$

$$K'_4 = \frac{K_6}{A_4} = -\frac{c_1B_4}{A_4} = -\frac{c_1h}{a_1 + c_1} < 0.$$

Checking signs of variables indicates that, in order for r' to be zero, at least one of the structural parameters must have a sign opposite to that postulated by Stein.⁸ Consequently, when Stein's model is modified to include error terms on (A3) and (9), his technique results in inconsistent estimates.

III. On The Interpretation of R

The discussion up to this point has been concerned with the problem of obtaining consistent estimates of the effects of R on capital movements. The logically prior question of the usefulness of such an estimate has been ignored. My conclusion is that, even if consistent estimates of K_4 were available, they would be of little value because R cannot be interpreted as representing the effects of any one variable.

Apparently, Stein is interested in the effects of R on capital movements because R is an approximation to the covered interest rate differential.⁹ Exchange market theorists have traditionally assumed that the size of the covered interest rate differential reflected the degree of speculation in foreign exchange markets. Stein, therefore, is interested in R as a proxy for speculation.¹⁰ His model, however, suggests that $R = A_1p^* - A_2[S(t-1) + T - w]$ reveals nothing about speculation until we know something about A_1 , A_2 , T , $S(t-1)$, and w . Unless we are willing to assume that A_1p^* is "large" and $A_2[S(t-1) + T - w]$ is "small," the assumption that movements in R reflect movements in p^* could be highly misleading. After a search of the foreign exchange market literature, I am left with the uneasy feeling that there is little "hard" a priori evidence on this subject; many people make this assumption mainly because it has been a traditional assumption.

It is not difficult to produce a plausible example in which the covered interest rate differential responds to something besides expectations about the future foreign exchange rate. Suppose that exports rise sharply and that

⁸ He assumes that g_1 , c_1 , h , a_1 , a_3 , and g_2 all are greater than zero [9, pp. 48-50]. I need not belabor the point that in order for all of the above restrictions on K'_4 to be satisfied, other complicated restrictions must be placed on the structural parameters. These will not be discussed.

⁹ If the constant term were zero and the coefficient of I were one in equation (28) in [9, p. 58], R would exactly equal the covered interest rate differential defined by Stein [9, p. 43].

¹⁰ Stein [9, pp. 41 and 64] explicitly interprets R as reflecting speculative pressures, as indeed he must unless he clings to nonoperational statements about R .

the buyers of exports finance their purchases with short-term credit. If those buyers always hedge, they will cover in the forward market. If the increase in exports is large enough, pressure on the forward market will result in a nonzero covered interest rate differential. R has moved and yet no speculative pressures necessarily exist! Anyone who uses R as a proxy for A_1p^* must assume that it is unlikely that a rise in exports will have a significant effect on R . It is certainly not evident to me why such an assumption is empirically reasonable.

In the absence of any persuasive arguments about the relative importance of variables determining the covered interest rate differential, I must conclude that the use of R as an explanation of capital movements is non-operational, i.e., it does not necessarily imply anything about the effects of any particular variable, like p^* .

DONALD G. HECKERMAN*

* The author is a graduate student at the Massachusetts Institute of Technology. He wishes to thank William Branson for his comments on several early drafts.

COMMENT III

During the past few years several attempts have been made to measure the interest sensitivity of short-term capital movements. In his recent article Stein [9] calls attention to many errors in earlier research on this subject and undertakes to correct them. But serious conceptual and empirical problems remain even in his work. Stein's basic two-equation regression model is of the following form:

$$Y(t) = \alpha_0 + \alpha_1 R(t) + \alpha_2 I(t) + u(t)$$

and

$$X(t) = \beta_0 + \beta_1 R(t) + \beta_2 I(t) + v(t).$$

Where, $Y(t)$ ≡ the change in the stock of U.S. short-term banking claims on foreigners from the end of month $t-1$ to the end of month t .

$X(t)$ ≡ the change in the stock of short-term banking liabilities to private foreigners, payable in dollars from the end of month $t-1$ to the end of month t .

$R(t)$ ≡ a speculation variable constructed by Stein.¹

$I(t)$ ≡ the U.K. 3-month Treasury bill rate minus the U.S. yield rate on new 3-month Treasury bills as of month t .

$u(t)$ and $v(t)$ are the stochastic disturbance terms in their respective equations. Implicitly, these regression equations assume that both R and I are exogenous variables. That is, from knowledge of α_1 and α_2 , one can predict the impact on Y of specified independent changes in R and/or I .

In this comment I shall ask in turn (1) whether R solely represents speculation and, given the way Stein has constructed R , whether it is meaningful to use I and R together as independent variables in a multiple regression

¹ For the precise calculation technique see Stein [9, pp. 57-59].

equation, (2) whether it is truly proper to regard R and I as exogenous variables in the context of an explanation of short-term capital flows, and (3) whether there are not logical variables, other than I and R , which will explain a larger portion of the variance in Y .

Speculation and Interest Sensitivity

The values for the speculation variable, R , constructed by Stein, are the residuals from a time series regression of the U.K.-U.S. interest differential, I , on the forward premium (—) or discount (+) of the British pound, X_2' .² Thus,

$$X_2'(t) = S_0 + S_1 I(t) + R(t).$$

R is simply an unusual forward premium or discount on the pound sterling, in the sense of not being accounted for by the interest rate differential. To contend that R represents only speculative pressure is incorrect: R may fluctuate in the absence of speculative pressure. Suppose that there is no fear of devaluation (of either the pound or the dollar), but that in a given month an exogenous increase occurs in the U.S. trade balance with Britain. If exporters are prone to hedge foreign accounts receivable, the demand for forward dollars by U.S. exporters will increase relative to the volume of forward dollars supplied by British exporters. The premium on the dollar will rise and will be registered as an increase in R . As R increases this should elicit a decline in the outflow of U.S. short-term capital because of the increased expense for U.S. capital-exporters in hedging their short-term pound assets. Thus we would expect to find Y and R negatively correlated, but not solely owing to speculative pressure. Similarly, exogenous changes in capital flows could give rise to a positive correlation between Y and R even in the absence of speculative pressure. Joint variation in Y and R has many sources, and is not uniquely related to speculative activity.

It is a requirement of least-squares regression that R and I be statistically independent. Stein himself points this out: "By the property of a least-squares regression, X_2 [which is the variable I] and the residual R are uncorrelated" [9, p. 55]. But, that being the case, must one not doubt the usefulness of a multiple regression in which R and I appear as the sole independent variables? Stein's interest sensitivity coefficient is not different from the one derived from the simple linear regression of capital movements on the interest rate differential below. Using Stein's basic model, least-squares regression on monthly data from November 1958 through October 1962 yields the following equation:

$$(1) \quad Y = 12.90 + 24.06I - 43.17R.^3$$

(11.50) (34.88)
 $r^2 = .06$

$D - W = 2.23$

² The notation used here is Stein's [9].

³ Because of some minor data differences, I have been unable to produce the precise results presented by Stein [9, pp. 62, 64]. However, the slight discrepancies do not affect the substance of the argument. The time period analyzed in this paper starts with November 1958 and ends with October 1962. The data are on a monthly basis. The interest rate data are from the *Federal*

Using I as the sole explanatory variable yields:

$$(2) \quad Y = 12.30 + 24.19I.$$

$$(11.57) \quad \bar{r}^2 = .05$$

$$D - W = 2.12$$

Stein's method, thus, has not corrected the capital flow interest differential relationship for speculative capital movements.

In Stein's criticism of the earlier works of Bell [2] and Kenen [7] he implies that he has indeed separated these effects and, thus, has come up with a pure interest differential coefficient. In his conclusion Stein states:

Bell found that the interest rate differential was not a significant variable. . . . One possible reason for our different results is the level of aggregation. . . . A more important reason is that he failed to take account of the speculative expectations which I took into account with my R variable [9, pp. 65, 66].

This "more important reason" by Stein's own analysis and description is invalid.

Are R and I Exogenous?

Stein recognizes [9, p. 43] that the forward premium on the pound is affected by capital flows and, hence, is endogenous. This in turn renders the covered interest rate differential an endogenous variable. He concludes that the covered interest rate differential cannot be used as an explanatory variable without bias. Yet Stein proceeds to use his index of speculative activity, R , as an additional explanatory variable. What is R ? The nominal label of speculation notwithstanding, R is nothing more than an unusual forward discount or premium on the pound. It is, indeed, an endogenous variable in the system. The same reasons used by Stein [9, pp. 43, 44] to show that the covered interest differential is not exogenous, apply *a fortiori* to Stein's R .

Stein's own writing is ambivalent as to whether I , the uncovered interest rate differential, can be treated as exogenous. He suggests a particular instance in which it most certainly was not exogenous, vis à vis capital flows. Specifically Stein states [9, p. 43], "As a result of the capital flow, the U.K. authorities raised interest rates. . . ." Since the data are generated by two-way interaction of interest differentials and capital flows, the estimates of the impact of changes in the interest rate differential provided by Stein's model are subject to a downward bias.

Interest Sensitivity in a More General Framework

In earlier studies of U.S. short-term capital movements, several authors have felt it appropriate to introduce variables representing trade [2][3]

Reserve Bulletin, the speculation data from Stein [9, p. 59] and the capital flow data from the *Treasury Bulletin*, Capital Movements. Section III, Table 2. The numbers in parentheses below the regression coefficients are the standard errors of their respective regression coefficients. \bar{r}^2 is the coefficient of determination corrected for degrees of freedom and $D-W$ is the Durbin Watson "d" statistic.

[5][7] and the domestic availability of short-term capital funds.⁴ Stein did not examine any such variables, presumably because he was principally concerned with the interest sensitivity of short-term capital flows. Yet, there is a major problem here in determining the net regression coefficient of any variable unless the specification of the model includes all the appropriate variables in the multiple regression. This is especially so in time series analysis, for time series tend to move in similar patterns, thus creating a high probability of multicollinearity.

It is, therefore, important to inquire what happens when Stein's basic regression equation of U.S. short-term capital movements is augmented by the inclusion of two other exogenous variables. These are: (1) the U.S. trade balance (T), and (2) monthly changes in the U.S. money supply (M).⁵ A large portion of U.S. short-term capital flows consists of trade financing. According to Bell [2, pp. 427, 428], "It would appear, then, that virtually all of the net outflow of U.S. short-term capital outflow before 1960, and 50-60 percent of the much larger outflow of 1960 and 1961 (and indeed the first half of 1962 as well) consisted of export finance." The following empirical tests take as the trade variable, the U.S. trade balance; on a priori grounds, the trade balance seems more appropriate than exports, given the net nature of the capital movements being analyzed here. The availability of short-term funds is measured as monthly changes in the U.S. money supply. One may think of banks as having a marginal propensity to invest in foreign short-term assets. The extremely high variance of this series precludes the possibility of banks lending these funds for longer periods of time. The results of Stein's basic model were given in equation (1). In all, only 6 per cent, after adjusting for the degrees of freedom, of the variance in U.S. short-term capital movements is explained—principally by I , which was significant at the 5 per cent level. R was not significant at even the 20 per cent level.

When T and M are introduced we obtain:

$$(3) \quad Y = -15.31 + 9.04I - 39.61R + 15.27M + .150T,$$

$$(14.36) \quad (33.62) \quad (6.23) \quad (.109) \quad \bar{r}^2 = .18$$

$$D - W = 2.19$$

and after dropping the variables I and R .

$$(4) \quad Y = -22.04 + 14.57M + .211T.$$

$$(6.17) \quad (.080) \quad \bar{r}^2 = .18$$

$$D - W = 2.10$$

Note that in regression 3, the coefficients of I and R are insignificantly different from zero. The monthly changes in the U.S. money supply, M , ap-

⁴ Kenen [7] considered this variable specifically as the amount of "U.S. net free reserves."

⁵ The data for these variables are from the *International Financial Statistics* of the International Monetary Fund.

pears as the explanatory variable to which Y is most strongly related: it is significant at the 2 per cent level. The trade balance coefficient is larger in relation to its standard error than are the coefficients of I and R , although it is not significant at confidence levels above 85 per cent. Equation 3, after adjustment is made for the degrees of freedom, explains 18 per cent of the variance of U.S. short-term capital movements, three times as much as the basic Stein model, and the interest differential variable no longer seems to be important.

Indeed, the separate test in equation 4, including only M and T , yields results that are as good as those in equation 3. Both variables are significant at the 2 per cent level and 18 per cent of the variance is explained, after making an allowance for the degrees of freedom. Therefore, on statistical grounds it would appear much more plausible to accept regression equation 4 instead of the basic model advanced by Stein.

Conclusions

In this comment I have attempted to make the following points which, in part or completely, invalidate Stein's results. (1) The variable R is not solely a speculation variable, but may fluctuate for reasons other than speculation. The use of R in Stein's basic model has no effect on the coefficient of the interest differential variable, I . (2) The variables R and I are endogenous variables and, therefore, their respective coefficients, as measured using Stein's basic model, are biased. (3) Other more truly exogenous variables explain more of the variance in U.S. short-term capital flows than do R and I , and when used in conjunction with R and I reduce the coefficients of R and I to a point where they are statistically indistinguishable from zero.

ARTHUR B. LAFFER*

COMMENT IV

In a recent article in this *Review*, Jerome L. Stein [9] attempted, among other things, to choose between the stock theory of international capital movements employed by Philip W. Bell [2] and the flow theory employed by Peter B. Kenen [7]. While Stein's recognition of the "simultaneity problem" (the simultaneous determination of the covered interest rate differential and capital flows) is a welcomed contribution, his treatment of the stock versus flow issue is objectionable. Clarification of this issue and correction of some errors that stemmed from Stein's misunderstanding of it are the objectives of this comment.

I. The Speed of Adjustment

The stock versus flow controversy arose because Bell [2] regressed the stock of U.S. short-term private claims outstanding on the level of interest

rate differentials, while Kenen [7] regressed the change in the stock of claims on the level of the differentials. Bell did not discuss his procedure and Kenen was somewhat cryptic.¹

This issue revolves around the *speed* at which economic units adjust their holdings of foreign assets in response to changes in interest rate differentials. Bell, by regressing stocks on levels of rate differentials, has implicitly assumed complete adjustment within a quarter to changes in rate differentials; if the relevant U.S. bill rate differential fell this quarter, and remained at the lower level in the future, it is assumed that U.S. investment in foreign assets would rise this quarter, but would not be further affected in following quarters. In contrast, Kenen's procedure of relating capital flows to the level of interest rate differentials assumes an extremely slow (technically zero) speed of adjustment. A permanent fall in the U.S. bill rate differential is expected to generate increases in U.S. investment abroad during this quarter and during all future quarters. Put another way, Kenen assumes (ignoring the constant term and other explanatory variables) that as long as there is a positive interest differential there will be a capital flow. Bell assumes that if the differential does not change—even if it is very large—there will not be a capital flow. While neither assumption is very likely correct, the former can be defended as an empirical approximation of a rapid speed of adjustment and latter, of a very slow speed of adjustment.²

This discussion of the Bell and Kenen assumptions can be formalized in terms of a Koyck-Nerlove distributed lag model as follows. In general, holders of an asset can be thought of as changing their stock of holdings during a period in response to the difference between their desired stock, S_t^* , and the stock existing at the beginning of the period, S_{t-1} .

$$(1) \quad S_t - S_{t-1} = k(S_t^* - S_{t-1}) \quad \text{where } k \text{ is the speed of adjustment.}$$

For simplicity, assume that the desired stock is linearly related to an interest rate differential, r , so that

$$(2) \quad S_t^* = \alpha_0 + \alpha_1 r_t$$

Then by substitution,

$$(3) \quad S_t - S_{t-1} = k\alpha_0 + k\alpha_1 r_t - kS_{t-1}$$

¹ In the only relevant passage in his report Kenen said: "By correlating these two types of data [capital flows and the level of interest rate differentials], we implicitly assert that a given interest rate difference will cause a given inflow or outflow of cash. One can conceive of an alternative hypothesis, linking the interest rates to total claims and liabilities, and changes in one to changes in the other. But this alternative would make sense only if we worked with absolute interest rates rather than with interest rate differentials" [7, p. 161]. (Interesting enough, Bell followed the exact reverse of the procedure that Kenen proposed. Bell regressed short-term claims outstanding on levels of interest rate differentials, but net purchases of foreign long-term bonds on absolute interest rates.)

² The appropriateness of the assumption depends in part on the length of the period of observation being used in the empirical estimation. For example, while the stock assumption might be very appropriate when working with annual data, it is probably very inappropriate when working with monthly data.

The flow theory which relates $S_t - S_{t-1}$ to r_t only, assumes that k is equal to zero, making S_{t-1} irrelevant.³ The stock theory, which relates S_t to r_t only, assumes that k is equal to one, again rendering S_{t-1} irrelevant (adding S_{t-1} to both sides of equation (3) gives a coefficient of $1 - k$ for S_{t-1} on the right hand side). An alternative to making either extreme assumption regarding k is to estimate equation (3), or its transformed counterpart that has S_t as the dependent variable.⁴ Stein [9, pp. 60-62] has inadvertently done the latter; the estimated monthly speeds of adjustment in response to changes in the U.S.-U.K. differential and his speculative variable are .07 for foreign investment in U.S. assets and .00 for U.S. investment in foreign assets. These results suggest that the flow theory might be a reasonable empirical approximation.⁵ This is, of course, quite consistent with Kenen's positive findings regarding the significance of interest rates and Bell's negative results.

II. Stein's Analysis

Stein, when attempting to resolve the stock-flow issue, mistakenly equated his general stock-adjustment equation [equation (3) above] to Bell's very restrictive stock (immediate-adjustment) theory. Stein failed to realize that estimation of a general stock-adjustment equation can yield empirical results that are consistent with *either* the stock or flow theories (or with neither). In fact, as was noted above, estimation of the stock-adjustment equation is a means of discriminating between the theories. This misunderstanding caused Stein much misery as he then felt it necessary to choose between his stock-adjustment and flow equations which are extremely similar. For example, compare the following equations of Stein [9, pp. 61, 62], where $SY(t)$ is the current stock of U.S. short-term banking claims of foreigners, $Y(t)$ is the corresponding flow, $SY(t-1)$ is the lagged stock, $R(t)$ is Stein's residual variable, and $I(t)$ is the current U.K.-U.S. 3-month Treasury bill rate differential:

³ Because the flow theory also assumes that an increase in foreign short-run interest rates relative to domestic rates generates a *perpetual* increased outflow of capital (assuming the differential remains unclosed), the long-run impact of an increase in the differential on the desired stock of assets, α_1 , is infinity. Thus r_t is relevant in equation (3), even when k is close to zero.

⁴ While the lagged stock formulation is an excellent theoretical device, its empirical usefulness is somewhat questionable due to the severe constraints imposed on the lag structure. The behavioral economic unit is assumed to adjust its holdings of an asset during a period by a constant fraction of the discrepancy between its long-run desired holdings and its existing stock the previous period, and the constant fraction adjustment is assumed to be the same regardless of which of a series of variables determining long-term desired holdings changes. For an empirical test of the appropriateness of these assumptions with regard to the demand for money, see Hendershott [4].

As an alternative to employing the stock-adjustment model one might regress capital flows on current and lagged changes in interest rate differentials, etc., allowing the data themselves to determine the lag structure. (This technique was employed in my test of the assumptions underlying the stock-adjustment model [4].)

⁵ My own limited experimentation also supports the flow theory as an empirical approximation. These experiments are to be reported in [6, Ch. 6].

$$(35) \quad SY(t) = \underset{(.0208)}{1.0005}SY(t-1) - \underset{(37.9192)}{43.8306}R(t) + \underset{(13.8128)}{23.765}I(t) + 11.5762$$

$$r = 0.9941$$

$$(37) \quad Y(t) = - \underset{(34.7920)}{51.9627}R(t) + \underset{(11.4715)}{23.1371}I(t) + 13.2214$$

$$r = 0.3518$$

The speed of adjustment *implied* by equation (35) is zero ($1-1.0005$), the same as that *assumed* by the formulation of equation (37). Not too surprisingly the regression coefficients are very similar (the coefficients of the interest rate differential are almost identical). There is no need (or basis) to discriminate between equations (35) and (37) because they say virtually the same thing—the capital flow is related to the level of the interest rate differential.

Stein's misunderstanding of Bell's stock theory also leads him to an erroneous explanation of why he found the interest rate differential to be a significant determinant of the U.S. stock of foreign assets but Bell did not. The two explanations that Stein provides [9, pp. 65, 66]—his analysis of aggregative data and his employment of the speculative variable—should lead him to a lower rather than higher estimate of the interest sensitivity than that obtained by Bell. As Stein notes [9, p. 47] there are substitution effects that *offset* part of the direct effect of interest rate movements and these might be missed in a disaggregative analysis such as Bell's.⁶ Similarly, Stein's speculative variable is designed to separate the speculative and interest rate effects, both of which would be attributed to interest rate sensitivity in an analysis such as Bell's. The reason for the difference in the Bell and Stein findings is that Stein uses the stock-adjustment formulation which, when the coefficient on the lagged-stock approximates one, is equivalent to Kenen's flow theory, rather than to Bell's stock theory.

PATRIC H. HENDERSHOTT*

* The author is a research economist at the Board of Governors of the Federal Reserve System. He gratefully acknowledges comments by Ralph C. Bryant on an earlier draft of this note.

⁶ Stein's conjecture [9, p. 57] that the aggregative approach is the only way of accurately measuring the total interest rate effect is incorrect. Disaggregation overstates the total interest rate sensitivity (by ignoring substitutive effects) only if coefficients for some sub-categories of capital flows are not estimated and thus not included in the summation of interest rate coefficients. Total summation nets out substitution effects.

COMMENT V

Jerome Stein's recent article in this journal [9] has made a significant contribution to the study of private international short-term capital flows. Its importance rests at least as much upon its methodological innovations and implications for future study as upon the conclusions which it presents. Stein's criticisms of the previous studies in this area are well founded, and

his development of a proxy measure of speculative influence is an interesting but unsuccessful attempt to differentiate quantitatively between speculative and interest-induced short-term capital movements. Because of the importance of this article and its probable influence on future studies, it seems necessary to raise a point concerning Stein's procedure of disaggregating capital flows into two groups, United States and foreign, using separate regressions to estimate the sensitivity of each.

Stein's rationale for this separation is that "There is no a priori reason why the coefficients of the U.S. capital equation should be the same as those of the foreign private capital equation, since different parties are involved" [9, p. 57]. While this is true, the nature of the short-term capital flows during the period ... do not solely reflect differences in the responsiveness of these parties. Stein's estimating equations (15 and 22) state that U.S. and private foreign capital flows are functions of an interest-differential variable (I), a variable measuring speculative influence (R), and a disturbance term.¹ The characteristics of the present international monetary system are such, however, that the independence between U. S. and foreign capital movements assumed by Stein's regressions does not hold.

The flow of private foreign short-term capital between the United States and foreign countries is not independent of the flow of U.S. short-term capital. That is, outflows of capital from the United States will in themselves generate a partial offset in the form of induced inflows into the United States. The widespread practice among American banks of requiring borrowers to hold a certain portion of their loans in the lending banks as compensatory balances, as well as the tendency for many foreign borrowers to keep a portion of their funds in the United States as working balances, means that an increase in the foreign assets of U.S. banks will usually generate a somewhat automatic though smaller increase in the banks' liabilities to foreigners.² This is particularly important in the case of the large capital flows between the United States and Canada.

The claims of Canadian banks upon banks in this country ... representing more than one-fourth of total foreign commercial claims ... are closely related to the volume of funds placed by U.S. residents ... in Canadian banks. ... A very large proportion of the liquid U.S. funds placed in Canada is reinvested in the United States. [10, p. 118.]

Thus foreign private capital inflows into the United States are, *ceteris paribus*, a positive function of the outflow of capital from the United States.³ The outflow of U.S. capital is, however, a function of the interest

¹ Equation (15), the stock equation also includes the previous period stock.

² This consideration may have had little effect on the conclusions of Stein's aggregative analysis, for despite "strong direct correlation for Japan and Canada ... all countries taken together ... yield [slight] inverse relationships" [7, p. 159]. It could, however, be highly important in the study of capital flows between the United States and individual countries.

³ See also Oscar Altman [1 pp. 536-37]; and Kenen [7, p. 159]. In fairness to Stein, it must be mentioned that a large portion of the U.S. funds placed in the Canadian market come from nonbank corporations and would, therefore, not be included in his data.

rate differential, which in turn is a major determinant of the size of the foreign capital inflow. Therefore, an independent variable in each of Stein's foreign capital flow equations is correlated with the disturbance term, and the least squares estimates of the coefficients of responsiveness of foreign and U.S. capital flows . . . do not accurately measure the relative responsiveness of U.S. and foreign investors. In particular, this "bias" leads to an understatement of the interest sensitivity of foreign investors and an overstatement of the sensitivity of U.S. investors. The inflow of foreign funds generated by an interest-induced outflow of U.S. capital will move in a direction counter to that which is dictated by interest rate differentials, diminishing the net movements of foreign funds. Furthermore, this return inflow would tend to replenish the uncommitted balances of domestic arbitrageurs and allow them to place even more funds abroad. The actual sensitivity of U.S. capital would then be overstated by the amount of this secondary outflow. If movements of capital from Canada to the United States were induced, the desire of Canadian banks to draw down their New York balances would again generate a flow of capital counter to the direction of interest-rate and/or speculative incentives, once more overstating the sensitivity of U.S. investors and understating the sensitivity of foreign investors. This structural relationship may be one of the reasons why Stein found that private foreign capital appeared considerably less sensitive to interest rate differentials than did U.S. capital.⁴

It should be stressed that this comment on Stein's methodology is an economic, not a statistical one. This structural relationship need not statistically bias the least squares estimates of the capital variable coefficients because the secondary movements noted above are directly ascribed to the independent variables. The point is that the coefficients of the capital variables do not accurately measure U.S. and foreign investors' responses. In addition, the coefficients of the U.S. capital equation will not be independent of the decisions of foreign investors and, vice versa, the coefficients of the foreign capital equation will not be independent of the decisions of U.S. investors.

He wishes to thank Professors William Branson, Alexandre Kafka, Alan Walters, and Leland Yeager for their helpful comments on earlier drafts on this paper. The underlying research was financed in part by the National Science Foundation and the American Bankers Association.

⁴ Stein estimates [9, p. 65] that if the U. K. interest rates were raised by one percentage point (covered) above the U.S. rate, U.S. capital outflows would increase by \$277 million per annum, while foreign private capital inflows would decline by only \$185 million per annum.

Short-Term Capital Movements: A Reply

Apparently, there is no criticism of my theory of short-run capital movements. What has been criticized is my statistical estimation procedure. Since I think that the statistical analysis has low explanatory power, I wel-

come criticisms of it. In this Reply, I shall evaluate the criticisms of Gray, Heckerman, Hendershott, and Laffer and indicate some possible lines of research.

I. *The Use of the R Variable*

Three models were considered in my paper, summarized by equations (14), (21) and (26); hence, variable R has three meanings. Corresponding to the first model, from eq. (11),

$$R_1 = A_1 p^* - A_2 S(t-1) - A_2 (T-w).$$

Corresponding to the second model, from eq. (20),

$$R_2 = A_1 p^* - A_2 (T-w).$$

Corresponding to the third model, from eq. (25),

$$R_3 = \frac{-g_2}{g_1 + h} Z.$$

It is obvious from the first two equations and it was stated explicitly on pages 52-53 that, in the first two models, R is affected by price expectations (p^*), the parameter of the basic balance function (w), and official purchases or sales (T). Only in the third model (i.e., R_3) can R be regarded as depending entirely upon price expectations. Unfortunately, I was guilty of misleading nomenclature when I referred to R as a "speculative" variable; and I hope this misunderstanding is now cleared up.

Heckerman (in particular) questions my estimate of R on the grounds that it is correlated with "the disturbance term." If that were the case, the estimates of the regression coefficients would be biased. I shall show that, in my model, the parameter estimates are unbiased. They would be biased had I chosen the specifications of his alternative model.

Solve R_1 for p^* and substitute this value into equation (14) to obtain:

$$(14.1) \quad S(t) = K_3 x_3(t) + (K_2 - K_1 A_2 / A_1) S(t-1) - (K_1 / A_1) R_1 \\ + (K_2 - K_1 A_2 / A_1) (T-w).$$

It would appear that "the disturbance term," in the estimating equation, is $(T-w)$ which would be correlated with R_1 , since it is contained in R_1 . But this is not the case, since a substitution for the values of K_1 , K_2 , A_1 , and A_2 (from footnotes 11 and 12) shows that:

$$K_2 - K_1 A_2 / A_1 = 0.$$

The statistical counterpart of (14.1) would be:

$$(14.2) \quad S(t) = b_0 + b_2 R(t) + b_3 x_3(t) + u_1,$$

where u_1 represents a set of disturbances beyond what is specified in the model. These disturbances are not $(T-w)$, and hence are not obviously correlated with $R(t)$.

Equation (14.2) is the equilibrium solution¹ of difference equation (14), given p^* and $(T-w)$. My method of estimation is not amenable to the criticism that R is correlated with the disturbance term u_1 .

There are several problems. First, there is no reason to believe that R is a very good estimate of $K_1p^* - K_2W$, for the reasons presented in footnote 13. Second, the value of $S(t)$ is not necessarily at its equilibrium, given p^* and $(T-w)$. For these reasons, I used

$$(15) \quad S(t) = b_0 + b_1S(t-1) + b_2R(t) + b_3x_3(t) + u$$

as my estimating equation. The (implicit) value of u reflects the disturbances that were not captured by the other variables.

Heckerman shows that if disturbances are inserted in each of the structural equations, (A3) and (9), then my method of estimating R_1 or R_2 would lead to biased parameter estimates. That is correct; but I did not use such a model. My method of estimation was related to the model I specified.

It is possible to try to estimate p^* and w , in equations (14) and (21), directly rather than indirectly through the use of the residuals R_1 and R_2 . I tried this approach with very little success. Let $p^* = v_1p(t-1) + v_2p(t-2)$, where $p(t)$ is the dollar price of the pound in period t . Let the exogenous parameter $w(t) = m_0 - m_1M(t-1)$, where $M(t-1)$ is the U.S. money supply lagged one period. Substitute these into equations (14) (or 21) and obtain:

$$(14.3) \quad S(t) = b_1S(t-1) + b_2M(t-1) + b_3x_3(t) + b_4p(t-1) \\ + b_5p(t-2) + u.$$

With respect to the corresponding flows $y(t)$, the regression equation was:

$$(21.1) \quad y = a_1x_3 + a_2M(t-1) + a_3p(t-1) + a_4p(t-2) + u.$$

These equations were estimated for both U.S. short-term capital and private foreign short-term capital.²

Variables $S(t-1)$ and $M(t-1)$ were the only significant variables explaining the stock of short-term liabilities to foreigners. No independent variable was significant in explaining the flow of short-term liabilities to foreigners.

The stock of U.S. short-term claims on foreigners was significantly related to $S(t-1)$ and $x_3(t)$. The regression coefficient of x_3 was \$35 million dollars per percentage point. The flow of U.S. short-term claims on foreigners was significantly related only to $x_3(t)$. A one percentage point rise in the U.K. minus the U.S. Treasury bill differential would raise the flow of U.S. short-term capital by \$27.3 million per month, (the value of t was 2.13). The interest sensitivity is close to what I obtained in the original article.

Laffer's use of the U.S. trade balance as an independent variable in estimating capital flows is undesirable. It is a dependent variable: a function of

¹ This assumes that $K_2 \neq 1$. See Part II below. The references to equations refer to the original article. Equations with "decimals" such as (14.1) have been added here.

² The data for a given date change from month to month in the *Treasury Bulletin*. Hence, I used the last reference to a given date, among a set of issues, as my value for a capital figure. If Laffer did not use this approach, he would obtain his slightly different results.

the price of foreign exchange; and it is linked to the short-term capital flow via an accounting identity. It also fails to show the role of opportunity costs in determining the rate at which foreign or domestic assets are accumulated or decumulated. There is no difficulty in "explaining" the flow of short-term capital movements in a statistical sense, by regressing the flow $y(t)$ on a set of ad hoc variables. High values of R^2 can always be obtained, with sufficient experimentation. What is so difficult is to estimate the values of coefficients which a reasonable model claims are significant. I have not succeeded in this task, and the challenge to estimate the coefficients still exists.

Laffer suggested that the interest rate differential x_3 and "disturbances" are not independent; and cited my own example. Hence, *any* estimate of the regression coefficients, in an equation containing x_3 , would be biased. This is indeed a serious problem, since we are interested in the effect of changes in a *policy* variable upon the capital flow. What would be the appropriate policy variable to use, which is also independent of the other exogenous variables? Despite the valid criticism, I still prefer to use the Treasury bill differential, since it is a major policy variable. It could be made independent of the current period disturbance, if we assumed that the capital flow during period t depended upon $x_3(t-1)$. But is such an assumption justified? Can a better policy variable be suggested? Much more work remains to be done, if there is to be a connection between the theory and the empirical data.

II. Stocks or Flows?

Gray is primarily concerned with my statement that: more fruitful empirical results are obtained by considering the interest rate differential as a determinant of the allocation of a *flow* of international capital among countries, rather than as a determinant of the allocation of a *stock* of capital countries. I prefer the stock theory, on logical grounds, as does Gray. But the question is which theory provides a better explanation of the data? Ideally, how would we decide which theory provides a better explanation of the data? Gray did not come to grips with this question. My approach is as follows.

The stock theory is summarized by:

$$(14) \quad \begin{aligned} S(t) &= K_2 S(t-1) + [K_3 x_3 - K_1 p^* + K_2 (T - w)] \\ &\equiv K_2 S(t-1) + A. \end{aligned}$$

If K_2 is a positive fraction, this difference equation has the solution for a given A ,

$$(14.4) \quad S(t) = \frac{A}{1 - K_2} (1 - K_2^t) + S(0)K_2^t.$$

On the other hand, if K_2 is not significantly different from unity we have a flow theory. Consequently, one test of the explanatory power of the stock theory is whether our estimate of K_2 (i.e., b_1) is significantly different from unity. Gray noted that no set of observations yielded a value of K_2 different

from unity. This does not mean that the two theories merge into one; but rather that the stock theory fails this test.

There is another way to try to ascertain which theory is inconsistent with the data. Suppose that the flow of capital consists of two parts: one arises from a stock theory (eq. 14) and the other from a flow theory (eq. 21). Hence, the composite flow:

$$S(t) - S(t-1) \\ = f(x_3, p^*, T-w) + s(\Delta x_3, \Delta p^*, S(t-1) - S(t-2), \Delta(T-w)),$$

where f is a weighted function of the flow theory and s is a weighted function of the stock theory. If we find that some of the variables (x_3 , etc.) in f are significant, but that none of the variables (Δx_3 , etc.) in s is significant, are we not led to question the stock theory? Since the variables in s were not significant, I concluded that the flow theory does better on empirical grounds.

My estimation techniques were not very successful in explaining capital flows; and eventually better techniques will be found to test my model (Part II). But regardless of which set of techniques is used, is Gray willing to accept my tests of stock and flow theories? If so, then where does he differ with my paper? If not, what alternative tests are offered?

Although P. Hendershott and I agree that the flow theory seems to fare better than the stock theory on empirical grounds, there are some methodological differences between us. First, he believes that the introduction of a distributed lag adjustment process is required to differentiate between the stock and flow theories. As Yair Mundlak [8] has shown, however, it is illicit to introduce in an arbitrary manner a distributed lag adjustment process. The logical structure of a model must imply its own dynamic adjustment. Equation (14) is the dynamic equation implied by my model; and the coefficients included in K_2 determine its stability properties. The procedure suggested by Hendershott may lead to nonsensical or misleading results in many cases, as Mundlak has shown. For this reason I cannot agree that I should have explicitly used the distributed lag approach that he suggests.

Second, his distributed lag equation (1) hardly suffices to define a flow theory. He states that: "The flow theory . . . assumes that k is equal to zero . . . the stock theory . . . assumes that k is equal to one. . . ." If k is equal to zero, then $S_t - S_{t-1} \equiv 0$, and hence there can be no net flow of capital. Does he really mean to define a flow theory in such a way as to preclude a flow of capital? Since the data show large capital flows, would he reject the flow theory immediately? He has fallen into this difficulty because he has arbitrarily introduced a distributed lag as a *deus ex machina*.

Diminishing Returns and Linear Homogeneity: Further Comment

While I have no desire to extend for extension's sake the already lengthy discussion in this *Review* regarding the consonance of increasing short-run physical marginal product with linearly homogeneous production, Robert Piron's recent "disproof" [3] of Stonier and Hague's "proof" [5, p. 226] of incompatibility is clearly in need of substantial correction.

Piron (rightly) considers the issue decided in favor of compatibility, noting that both Nutter's [1] and Rowe's [4] linearly homogeneous production functions exhibit a range of increasing marginal product for the variable factor. Wondering, then, where Stonier and Hague "went wrong," Piron (wrongly) concludes that "the persuasiveness of [their] proof seem-

ingly lies in the fortuitous choice of the fixed value for input Y ," that the factor input combination is "placed correctly" on the equal product map so as to fit the proof, and that by "badly" placing the input combination it is possible to negate their geometric proof. Specifically, Piron argues that "... had more isoquants been drawn, ... the demonstration of monotonically declining marginal product for X could prove difficult indeed" [3, pp. 185-86].

What follows is a demonstration of the proposition that it was not "the inherent shortcomings of plane geometrical proof" [3, p. 186] that led Stonier and Hague to a false generalization, but rather the fact that—in utilizing plane geometry—they restricted themselves to a consideration of downward-sloping convex isoquants. They did so on the ground that isoquant ranges that are upward sloping cannot contain equilibrium positions [5, p. 213]. Although downward-sloping convex isoquants, together with the linear homogeneity assumption, do imply diminishing returns (i.e., a convex production surface) over that particular range of inputs, it is nonetheless true that differently shaped or sloped isoquants would have yielded them different results. This is so because the shape and direction of slope of isoquants reflect the shape of the *linearly homogeneous* production surface, and thus the behavior of marginal product.

Following Stonier and Hague's analysis, assume a linearly homogeneous production function. Consider *any* combination P of fixed-factor Y and variable-factor X , as in Figure 1. P is necessarily a point on some isoquant with a value, say, of Q units. We assume isoquant Q to be convex to the x -axis. In attempting to determine the behavior of the marginal product of X , Stonier and Hague address themselves to the following question: Will it take a larger, smaller, or the same increment of X to reach isoquant $Q+\bar{k}$ units from isoquant Q , as it took to move from isoquant $Q-\bar{k}$ units to isoquant Q ?

A ray OR may be drawn from the origin through point P . OR will intersect isoquants $Q-\bar{k}$, $Q+\bar{k}$, and $Q+2\bar{k}$ at points S , V , and W respectively. The assumption of linear homogeneity ensures that $SP=PV=VW$. Consider a tangent to isoquant Q at point P . If the isoquant is *downward sloping*, it follows that the tangent to Q must extend from P to the northwest and southeast, as does tangent T_2 in Figure 1. Linear homogeneity implies that the marginal products of X and Y are homogeneous of degree zero, so that tangents T_1 through S , T_3 through V , and T_4 through W will be parallel to tangent T_2 , and will thus intersect a horizontal of height \bar{Y} drawn through P —say at A , C , and D respectively. Therefore, $AP=PC=CD$. Since all points (excluding S but including E) on isoquant $Q-\bar{k}$ must lie to the right of tangent T_1 , and all points (excluding V but including M) on isoquant $Q+\bar{k}$ must lie to the right of tangent T_3 , EP —the increment of X (Y constant) required to move from isoquant $Q-\bar{k}$ to isoquant Q —is necessarily less than AP , while PM —the increment of X required to move from isoquant Q to isoquant $Q+\bar{k}$ —must be *greater* than PC and therefore AP .

Is this demonstration of diminishing returns merely a result of "correctly placing" point P ? In particular, if we consider a further move from point M on isoquant $Q+\bar{k}$ to point U on isoquant $Q+2\bar{k}$, would Piron's assertion

Z but including P) on isoquant Q lie to the right of tangent T'_2 ; similarly, all points (excluding F but including U) on isoquant $Q+2\bar{k}$ lie to the right of tangent T'_4 . Therefore, $PM < JM = ML < MU$. And $EP < PM < MU$ reflects the monotonic decline of marginal product over input ranges of a linearly homogeneous production function characterized by *downward*-sloping convex isoquants.

But suppose that the relevant isoquants are *upward* sloping. Granted that these segments will not contain equilibrium points, it is nevertheless true

FIGURE 2

that linearly homogeneous production in itself does not exclude the possibility that such ranges may exist. What do upward-sloping convex isoquants—within the context of linear homogeneity—tell us about marginal productivity?

Precisely the same kind of analysis as above can be used to demonstrate *increasing* marginal product in the *upward*-sloping convex isoquant range of linearly homogeneous production. In Figure 2, the tangents and lettered points refer to isoquants with values comparable to those in Figure 1. However, the assumed shape of the isoquants imply northeast-southwest sloping tangents, and all relevant isoquant points are to the left of their respective tangent lines. $EP > AP = PC > PM$. Further, $PM > JM = ML > MU$. Thus, $EP > PM > MU$ demonstrates monotonically increasing physical marginal product.

In contradiction to Piron, the foregoing demonstrates that the tools of plane geometry are sufficient to determine the direction of movement of marginal product in the case of linearly homogeneous production. The

analysis could be extended to a consideration of isoquants that are concave to the x -axis; however, the results may be anticipated by taking note of three conditions that hold for the linear and homogeneous production function [2, p. 752]. Given such a function $q = \phi(x, y)$:

$$(1) \quad \phi_x = q/x - (y/x)\phi_y \quad (\text{Euler's theorem})$$

$$(2) \quad dy/dx = -\phi_x/\phi_y$$

and therefore,

$$(3) \quad d^2y/dx^2 = -(q/y)^2 \phi_{xx}/\phi_y^3$$

While it is true that the shape of the production surface is generally not revealed by isoquant analysis (e.g., convexity of isoquants does not in itself establish convexity of the production surface), the above conditions nevertheless imply that convexity and slope of isoquants do reflect the convexity of the linearly homogeneous production surface, and thus the behavior of marginal and average productivity. Consider Table 1. The above conditions

TABLE 1

| | $d^2y/dx^2 > 0$ (isoquants convex to x -axis) | $d^2y/dx^2 < 0$ (isoquants concave to x -axis) |
|---|--|---|
| $\phi_x > 0, \phi_y > 0$ (downward-sloping isoquants) | $\phi_{xx} < 0$ (diminishing marginal product) $\phi_x < q/x$ (diminishing average product) | $\phi_{xx} > 0$ (increasing marginal product) $\phi_x < q/x$ (diminishing average product) |
| $\phi_x > 0, \phi_y < 0$ (upward-sloping isoquants) | $\phi_{xx} > 0$ (increasing marginal product) $\phi_x > q/x$ (increasing average product) | $\phi_{xx} < 0$ (diminishing marginal product) $\phi_x > q/x$ (increasing average product) |

(2) and (3) together imply diminishing marginal product for variable factor X if and only if the relevant isoquant ranges are (a) downward sloping and convex to the x -axis, or (b) upward sloping and concave to the x -axis. Similarly, increasing marginal product for X emerges if and only if isoquants are (a) upward sloping and convex to the x -axis, or (b) downward sloping and concave to the x -axis. (Thus, Piron's statement [3, p. 186] that Stonier and Hague's equal product map—reproduced as his Figure 2—"could well represent a picture of the [increasing marginal product ranges of the] Nutter or Rowe functions" is incorrect, since the relevant isoquants are both downward sloping and convex to the x -axis.) Finally, conditions (1) and (2) together imply that only isoquants that are downward (upward) sloping reflect diminishing (increasing) average product.

Reply

Saraydar correctly demonstrates that the Stonier-Hague proof can be extended to any number of isoquants. However, his assertion that "... the foregoing demonstrates that the tools of plane geometry are sufficient to determine the direction of movement of marginal product in the case of linearly homogeneous production" is much too confident.

Downward-sloping, "correctly" curved isoquants, coupled with linear homogeneity, do, and I stand corrected on this point, provide sufficient conditions for a geometrical proof of monotonically declining marginal products. But, and here Saraydar is again correct, these are merely conditions defining a convex production surface. It is the convexity of the surface which provides the sufficient condition for falling marginal products, however, not the linear homogeneity property. This latter point was amply demonstrated in this *Review* earlier. Thus, where Stonier and Hague "went wrong" in assuming that linear homogeneity was sufficient for falling marginal product, was in choosing for their example the particularly fortunate case of a convex production function.

Had they instead used a linearly homogeneous, nonconvex production function, i.e., one which, in particular, generated downward-sloping "humped" isoquants as in the Nutter-Rowe examples, the geometrical proof of monotonically declining marginal products or of any behavior of marginal products, would have been exceedingly trying.

The Demand for General Assistance Payments: Comment

In a recent article published in this journal [2], C. T. Brehm and T. R. Saving (henceforth BS) argued that the demand for General Assistance Payments¹ can be formulated as a special case of the demand for leisure, and assuming potential relief recipients are as rational as the rest of the popula-

¹ A class of public relief or welfare benefits that are not federally subsidized. Henceforth referred to as GA.

tion, that higher levels of benefits lead to a greater demand for them. Although they carefully disclaimed any policy conclusions [2, p. 1015], BS in effect revived the view that high benefits encourage sloth, a view that antedates Marshall and Pigou, whom they cite [2, pp. 1001-3], and may also be found in the Report of the Poor Law Commissioners and in the economic tales of Harriet Martineau.² BS reformulated the argument with the use of indifference curve analysis, derived a demand curve for GA, and estimated its parameters in an econometric study. The results of their empirical analysis appear to indicate that the amount of GA taken in the several states is positively related to the level of benefit payments. On a close examination of the empirical work, we discovered that BS had made a significant error either in compiling or interpreting their data. With the correction of this error the observed positive association between the level of GA and the number of recipients, a relationship crucial to their analysis, completely evaporates. Without this empirical support the demand for leisure model of the relief environment is open to serious question.³

Empirical Findings

Let us begin with a brief review of the BS empirical model and results. The demand function derived by BS relates the per cent of a state's population receiving assistance payments (N) to the following independent variables: average monthly payment per recipient (P), average monthly manufacturing wage in the state (W), the rate of insured unemployment in the state (U), and nonagricultural employment in the state (NA), [2, p. 1012]. Equations employed in the empirical analysis were of the ratio form:⁴

$$(3.21) \quad N = a_1 + b_{11} \left(\frac{P}{W} \right) + b_{21} U$$

$$(3.22) \quad N = a_2 + b_{12} \left(\frac{P}{W} \right) + b_{22} U + b_{32} NA$$

and of the linear form:

$$(3.23) \quad N = a_3 + b_{23} U + b_{43} P + b_{53} W$$

$$(3.24) \quad N = a_4 + b_{24} U + b_{34} NA + b_{44} P + b_{54} W$$

P is the critical variable in the analysis. A positive significant value was predicted by BS for the coefficient of this variable in equations (3.23) and (3.24) and for the coefficient of P/W in equations (3.21) and (3.22). This result was apparently obtained in the BS calculations. It is our contention that the predicted behavior was not actually observed, and that the BS re-

² See Blaug's work on the discrepancy between data and conclusions in the study made by the Poor Law Commissioners under Nassau W. Senior's guidance [1, pp. 231-33] and Martineau's "Cousin Marshall" [3, pp. 103-6, 110-122, 129, 130-32] and "The Parish" [4, pp. 209-10].

³ We are currently developing alternative models of relief choice.

⁴ Subscripts i and j for state and sample year identification are omitted here for purposes of simplification.

sult is very probably the consequence of a misreading of the tables attached to the basic data or an error in model construction.

Perhaps the best way to explain the BS error and to clarify the empirical problems in this matter is to chronicle the history of our research. In the text of their paper, BS considered "the number of general assistance recipients as the relevant dependent variable. . . . Data have been collected on numbers of G.A.P. recipients on an average per-month basis. . . ." [2, p. 1007] We were, at first, unable to duplicate the results given in the original article since data on *recipients* of GA for the years 1951 through 1959 did not, apparently, exist in any published form, whereas data on *cases* were easily available in the *Social Security Bulletin* [8] and the *Statistical Abstracts* [7]. The citation given in the article was clearly an error, and we wrote to BS to ask for clarification. In reply, Brehm referred us to the *Social Security Bulletin* and *Statistical Abstracts*. On a hunch, we calculated regressions on the BS model using *case* data for their *recipients* variable. Our results approximated theirs and it became clear that BS used *case* data in their work. The distinction between *case* and *recipient* is important here. A recipient is always one person. A case consists of one or more recipients of a particular category of public assistance, and may comprise an entire household, part of a household, or one person. Definitions of GA case units, however, differ among states, and the GA case cannot be identified with a decision unit such as a household or family. In any event, payment per case cannot be considered a valid measure of benefit levels. Surely, \$50 per month for a case unit of three individuals represents a lower level of benefits than \$50 per month for a case unit of one person. Hence, when we discovered a considerable amount of state-to-state variability in the number of persons per case, what had at first appeared to be a minor error in labeling assumed substantive importance. When we adjusted the case data to a recipient basis and recalculated the regressions, we discovered that the positive relationship between the benefit level and the proportion of the population receiving such benefits disappeared.

In the paragraphs below we shall present the data and show the point at which the error was made. The significance of the error will first be shown crudely with the aid of scatter diagrams and then more precisely with the use of regressions recalculated with the correct data. This will be done in detail for a single representative year, 1959, and, to conserve space, in somewhat less detail for the rest of the period covered by the BS study. Finally, regressions on the BS model will be calculated for 1961–63 since actual recipient as well as case data are available for those years.

Data on individual recipients are available only for 1961 and subsequent years. We used 1961 figures to calculate a recipients-per-case measure for each state to correct the case data for the BS sample period.⁵ Table 1 con-

⁵ We chose 1961 as the basis for adjustment as it is the year with adequate data that is closest to the sample period. Recipients-per-case ratios do not change appreciably in later years, and our analysis assumes that they remain close to 1961 levels in earlier years as well. Federal programs instituted in 1961 reduced the number of GA recipients but apparently did not alter the relationships discussed in this study. Attention must be also directed to the poor quality of state data used both by us and by BS. Federal statistical standards do not apply, and data are not always comparable from state to state.

FIGURE 2

tains the data for 1959 presumably used by BS: average payment per case (Column 1) and number of cases as a per cent of state population (Column 2). The recipients-per-case ratio is given in Column 3, and Columns 4 and 5 contain the case data adjusted to a common recipients basis. Thus, where Colorado might seem to have a high benefit level, \$47.59 per case, as compared to \$15.05 per case for Mississippi, the differences disappear when the data are placed on a common basis: \$11.99 per recipient in Colorado and \$11.33 per recipient in Mississippi. The payment-per-recipient measure approximates the measure of benefit levels that the relief client will take into

account.⁶ The effects of the correction are quite apparent when we display the data in scatter diagrams. In Figure 1 *cases* as a per cent of population are displayed on the ordinate (the letters identify the states—see Table 1). The positive relationship of the BS study is easily detectable. When the data are corrected to show *recipients* as a per cent of population and average payment per *recipient* (Figure 2) the scatter shows no such relationship.

⁶ In our exposition we have followed BS who, from the wording in their text, appeared to consider the recipient (individual) to be the relevant economic unit. BS may, perhaps, have used case data with the intent of developing a decision-unit or household model. However, the corrections we have made apply even if one wishes to develop the analysis in these terms. Case data must be weighted by case size to obtain comparability among states and, as we have shown, payment per recipient is an appropriate measure of benefit levels, whereas payment per case is not. Of course, a more nearly perfect measure of benefit levels can be devised by taking into consideration the actual formulae applied by relief administrators to determine budgetary needs, but this is beyond the scope of our Comment.

Figure 2 portrays the true relationship. The positive association seen in Figure 1 is spurious and a purely arithmetic consequence of nonuniformity in case definitions among the states.

We turn next to the correction of the BS regression results. The correction of regression equations for the representative year 1959 is shown in Table 2. The rows of the table are broken into four sections, corresponding to equations (3.21, 3.22, 3.23, and 3.24) above. Each section contains three subdivisions: the first has the original BS results, the second has our approximation of the BS equations using *case* data, and the third subdivision contains the corrected regressions using *recipient* data. We employed single equation, least squares in estimating, rather than the Aitkin-Zellner technique used by BS. Exact duplication of their empirical procedures was not warranted; our correction, since it involves back-extrapolation from current data, is undoubtedly more accurate for the later years of the BS sample than for the earlier years.

We see first a close correspondence between the BS results and our regressions using "incorrect" data. Coefficient signs, magnitudes, and levels of statistical significance correspond closely; the minor differences are attributable to the different estimation techniques and to our use of single monthly observations rather than annualized data.⁷ The "correct" regression, however, reveals a much different type of behavior than that hypothesized by BS. The highly significant positive relationship between the per cent of population taking assistance and the benefit level disappears (see Columns 1 and 4). In fact, a negative sign crops up and the other coefficients take on strange values. R^2 and F fall drastically from their levels in the "incorrect" regression. (Note, in particular, the value of R^2 in equation 3.22.)

Corrected results for the earlier years of the sample, 1951-58, are presented in Table 3. To conserve space, only R^2 , F , and coefficient values and levels of significance for P and P/W are given. Values for these statistics are given in the columns of the table for each year of the sample, while the rows are arranged in blocks of three cells. As before, the first cell of each block contains the original BS result, the second cell contains the corrected regression. Again, recipient data were constructed by back-extrapolation of the 1961 recipients-per-case ratio. Although it would be foolish to put much reliance on the accuracy of our correction for the earliest years of the sample, it is again clear that no positive significant relationship exists between the number of recipients and the benefit level. A negative sign was observed in all runs. About half the time the values were significant.

Finally, we calculated regressions on the BS model using the more complete data available for the sample period 1961-63. Table 4 follows a format similar to that of Table 3 and contains results in regression equations calculated first with case data and second on the correct basis with current recipient data. The crucial parameters, the coefficients of P or P/W , are statistically insignificant and usually negative when recipients data are used, and again, R^2 and F decline precipitously.

⁷ We were not able to obtain recipient data to correspond precisely with the annualized data used by BS.

Summary and Conclusions

Since empirical evidence does not support the BS hypothesis, their "demand for leisure" approach and its theoretical underpinnings must be questioned. It seems to us that the key issue is one of choice. BS characterize the general assistance programs as offering a voluntary income alternative to work: "... qualifications [for GA eligibility] may be met by a deliberate action of the consumers and thus fall within the scope of our [BS] analysis" [2, p. 1007]. Under typical conditions, however, the choice is not effectively offered. The aid recipient is not permitted simply to opt for leisure. He is generally required (not "allowed") to work if able to work and work opportunities exist either in the market place or in work projects. In practice, the case worker controls a budget that he is likely to judge inadequate relative to legitimate demands for assistance at allowable benefit levels and he may be motivated to cut off from assistance those who could work but who would rather not. In effect, the BS analysis seeks to describe voluntary behavior in a situation in which restricted behavior is the general rule.⁸ This is not to say, of course, that disincentive effects may not exist in specific cases where standards of control are loose and where certain individual benefits may be high enough to encourage chiseling (averaged data may conceal instances of high benefits). On the whole, however, the BS disincentive effect can be dismissed as a significant consideration in policy. The GA recipient may, indeed, "be like the remainder of consumers . . . and react to economic incentives" [2, p. 1018], but only if a meaningful choice is offered to him. The relief controversy in Newburgh, N. Y.⁹ may be a good illustration that a model based on individual choice is not appropriate where such choice is absent.

BRUNO STEIN AND PETER S. ALBIN*

* The authors, respectively associate and assistant professor of economics at New York University, wish to thank their colleagues in the Faculty Research Seminar for their valuable suggestions, and the Institute of Labor Relations for its financial support. The calculations were performed on the CDC 6600 at the Courant Institute.

⁸ Alternatives to GA that are actually open are the following: (1) to work for less than the GA social minimum income, a choice made by people whose discount k [2, p. 1004] is high; (2) as a family unit, to work an unusually large number of hours per week, e.g., by putting school age children to work; (3) to participate in private rather than social redistribution of wealth, such as charity or theft; (4) to starve. It may be useful to note, at this point, that the average national level of GA benefits is in the neighborhood of \$22 per month per recipient.

⁹ On July 17, 1961, after a thorough and somewhat unsympathetic analysis of 1300 recipients of all forms of public assistance, the city found one man who might—possibly—be physically able to work [5, pp. 38–39]. Recent experience in Pennsylvania suggests that a social investment model may be a more appropriate tool of analysis. In that state, increases in benefit levels to finance dignified and unencumbered entry into the labor market were successful in reducing the absolute number of individuals on the relief rolls [6, p. 1211]. This raises an old question: do low benefit levels actually increase the dependence of the relief population on assistance?

The Demand for General Assistance Payments: Reply

It is gratifying to see that our article on the general assistance program has generated some interest in this problem by other economists. The question of the extent that Public Assistance programs are self-defeating is still an open one and, we believe, an area in which the application of economic analysis has been sorely lacking. Unfortunately, while Stein and Albin have discovered a problem in the data we used, they have not succeeded in removing this flaw. Thus, their results are as open to question as our original results. Moreover, when the problem they are concerned with is properly taken account of, the conclusions we reached in our original paper are substantiated.

Essentially, the Stein and Albin argument may be stated in the following way. The data we originally used were on a case basis with a case being defined as a group of people, usually a family, who pool their resources and live as a single unit. We then interpreted the case unit as the decision-making unit, in general a correct conclusion, and applied the theoretical argument we developed to this unit. However, we did not anticipate that subsequent data on total number of persons in families being assisted (called recipients by HEW) would vary by state in such a way that the average assisted family size would show significant differences from state to state. (As it turns out, there is good reason for this. We should have seen this point immediately.) Of course, if the level of the general assistance payment is independent of family size, the differences in average family size would be irrelevant. However, this is not the case and, hence, Stein and Albin's suggestion for expressing everything on a HEW recipient basis is justified. Stein and Albin then proceed to use data on total persons in assisted families (HEW recipient) for the period 1961-1963 and their ("correct"?) results indicate that no relationship exists between "recipients" and levels of payments per recipient.

Now we reach the crux of the problem. The so-called "correction" that Stein and Albin have made is inappropriate for two reasons. First, their correction fails to account for the problem they have discovered because it

fails to consider the reason for the problem. Second, a change in the Social Security Act in May 1961, of which Stein and Albin should have been aware but apparently were not, raises a serious question concerning the relevance of the data they use. We now discuss each of these points.

Problems with the Stein-Albin "Correction." Stein and Albin assume (as we did also) that all persons receiving general assistance fit into the theoretical model we described in our paper. In other words, they assume that each recipient could make the choice between work and general assistance. However, this is not the case. More importantly, the degree to which this assumption is in error differs from state to state in a systematic manner and accounts, in large part, for the differences between the states in average assisted-family size. In particular, differences in the scope of the general assistance program between the various states and, hence, in the ease with which someone who has the work-assistance option can get on the assistance rolls, will affect the proportion of all recipients to which the theoretical apparatus applies. For example, all states use general assistance to assist the aged and disabled but not all states allow the able-bodied to be on the rolls. Thus, the more restrictive the rules the fewer the able-bodied who will be aided. Since the aged and partially disabled are generally aided on a single-person basis, the states with restrictive rules will tend to have a smaller number of recipients per case. What needs to be done is to remove payments to single-person cases and the single-person cases from the study since these do not reflect the theoretical structure. Of course, if these problems were unrelated to magnitude of assistance payments, this adjustment would not affect the results. But, this, as we shall see, is not the case.

The Change in the Law. In May 1961, Congress amended the Social Security Act to provide federal aid to those states wishing to extend their program of Aid to Dependent Children to families with an unemployed member present (this program is referred to as ADC-U). This gave the states the opportunity of substituting a partially federally supported program for an entirely state supported one; that is, taking families on general assistance because of unemployment and transferring them to the ADC-U program. That the states have been doing this is well documented by their own welfare agency reports. The importance of this change in the law is that it has systematically removed from the general assistance rolls the very people for whom the theoretical model applied; those with the work-assistance choice. But, the years for which Stein and Albin have data are subsequent to the change in the law and, hence, the model should be expected to perform badly with their data.

"Correcting" the "Correction." As we have indicated above, the data we used in our original paper were inappropriate and needed to be adjusted for the single-person cases. We were able to obtain data on the number of one-person cases and the payments to one-person cases for the month of December, 1959 from the Department of Health, Education and Welfare. We then subtracted the one-person cases from the total persons in assisted families and subtracted the payments to one-person cases from the total payments. Unfortunately, these data were available for only 34 of the 48 states we

used in our original work. In addition, this correction did not remove all the variation in the average assisted family size so we followed Stein and Albin's lead and used total recipients in the *ith* state as a percentage of population in the *ith* state (corrected for one-person cases, of course) as our dependent variable and payments per recipient as our primary independent variable. We also included the rate of unemployment and two dummy variables that indicate the ease of getting on the welfare rolls. We ran the following regressions.

$$(1) \quad R_i^* = a_1 + b_{11}P_i^* + b_{12}U_i + b_{13}D_{1i} + b_{14}D_{2i}$$

$$(2) \quad \ln R_i^* = \ln a_2 + b_{21} \ln P_i^* + b_{22} \ln U_i + b_{23}D_{1i} + b_{24}D_{2i}$$

where:

R^* = Recipients (corrected) in the *ith* state divided by population in the *ith* state.

P^* = Assistance payments per recipient in the *ith* state.

U = Unemployment rate in the *ith* state.

D_1 = A dummy variable taking the following value:

0—if *ith* state has no residence requirement.

1—if *ith* state has a residence requirement.

D_2 = A dummy variable taking the following value:

0—if any kind of need qualifies.

1—if continuing or emergency needs qualify.

The results were as follows:

$$(1) \quad R_i^* = -0.942 + 0.177P_i^* + 0.536U_i - 1.60D_{1i} + 2.99D_{2i};$$

$$(3.22) \quad (0.111) \quad (0.579) \quad (1.35) \quad (1.74)$$

$$R^2 = 0.154$$

$$(2) \quad \ln R_i^* = -0.552 + 0.773 \ln P_i^* + 0.200 \ln U_i - 0.209D_{1i} + 0.318D_{2i};$$

$$(0.511) \quad (0.317) \quad (0.456) \quad (0.146) \quad (0.182)$$

$$R^2 = 0.228$$

The standard errors are presented in parentheses below each coefficient.

As is apparent from the results the assistance payment has the right sign in both cases. It is significant at the 12 per cent level in equation (1) and at the 2 per cent level in equation (2). By way of comparison with our original results, we show below the elasticities of welfare recipients with respect to

payments for these two equations (1) and (2) (above) and our previous estimates ([3.21]–[3.24]).

TABLE 1—ELASTICITIES OF WELFARE RECIPIENTS WITH RESPECT TO WELFARE PAYMENTS (1959)

| Equation | Elasticity |
|----------|------------|
| [1] | 0.57 |
| [2] | 0.77 |
| 3.21 | 0.67 |
| 3.22 | 0.53 |
| 3.23 | 0.82 |
| 3.24 | 0.79 |

As is readily discernible from the table, the newly estimated elasticities differ very little from the previous estimates. In addition, the coefficient of the payments variable is much more significant than the coefficient of unemployment in both regressions. This result is also similar to the results obtained in our previous paper. Thus, it appears that in spite of the problem uncovered by Stein and Albin our original results stand. One thing is clear, however, and that is that this area could stand a closer examination than economists have given it.

Errata

In the article by Richard R. Nelson, "Full Employment Policy and Economic Growth" (*American Economic Review*, December 1966, pp. 1178–92), many (but not all) subscribers' copies contained a number of typographical errors which resulted from the breaking-off of parts of certain characters as the printing of the issue proceeded. Thus the dots over several variables, intended to mark them as time derivatives, were omitted from a number of expressions. The omissions occur in (2), (7), (7a), (10), (11), (12), (12a), (12b), (12c), (13), and (14); in other expressions in footnotes 2 and 8 and on pages 1189 and 1190. In almost all cases, these are easily identified, for the omission of the dots makes the numerator and denominator of certain terms in the expressions identical.

BOOK REVIEWS

General Economics; Methodology

Analytical Economics. By NICHOLAS GEORGESCU-ROEGEN. Cambridge, Mass.: Harvard University Press, 1966. Pp. xvi, 434. \$12.95.

This collection of twelve papers first published between 1935 and 1960 together with a major new essay is a useful addition to current economic literature. It is certainly fitting that the previously scattered works of an important contributor to economic theory, especially in its mathematical formulations, should be assembled for ready access of today's students—both those currently in graduate schools and those whose degrees were awarded some time ago.

The republished essays are presented in Parts II to IV of the volume and are entitled, respectively, "Choice: Utility and Expectation," "Special Topics of Production," and "Economic Development." These are careful, perceptive, and eloquent expositions of important developments in economic thinking combined with frequent original insights and formulations. The author's ability to bring forth revealing thoughts from past literature in many fields while always taking a fresh critical look at the central issue under consideration is a rare gift. Thus Professor Samuelson's accolade, contained in his foreword to the book, "a scholar's scholar, and economist's economist" is well deserved.

While these virtues are still visible in the new essay, this work appears generally less rewarding to the present reviewer. Perhaps this is partly explained by disagreement with the main theme, but whether or not there are sound reasons for disagreeing will have to be judged by each reader. Interested readers should, of course, consult the essay itself since the account given here necessarily reflects a number of the reviewer's opinions and such a brief summary, even if ideally constructed, could convey only a small fraction of the discussion.

After some introductory speculation about the very early origins of science, the author indicates his conception of science and introduces the theme that economics is not a theoretical science. It is explained that theoretical science deals with arithmomorphic concepts (having basic properties similar to real numbers) which cannot encompass the varied phenomena essential to economics. Much of economics requires dialectical concepts which overlap with their opposites and therefore cannot be successfully handled by logic. This development is sketchily illustrated in the quotations below. Extended direct quotations are numbered to facilitate later reference to some of them.

1. It is clear then that the *causa materialis* (again, in the Aristotelian sense) of science is stored communal knowledge, that is, the body of all descriptive propositions available to any member of a community and believed to be true according to the criteria of validity prevailing at the time of reference. To take this equation as a definition of science would be patently inept. On the other hand, we must agree that the equation is valid

for all times and places, from the earliest cultures to those of today. Furthermore, the point disposes of the view that science is the opposite of description. On the contrary, science cannot exist without description. [pp. 3, 4]

2. By logical sorting, all propositions, P_1, P_2, \dots, P_n , already established in any particular field of knowledge can be separated into two classes (α) and (β), such that (1) every β -proposition follows logically from some α -propositions, and (2) no α -proposition follows from some other α -propositions. This logical sorting represents the inner mechanism by which a scientific theory is constructed and maintained. Theoretical science, therefore, is a catalog which lists known propositions in a logical—as distinct from taxonomic or lexicographic—order. In other words, we have a first equation

“Theoretical science” = “Logically ordered description.”

Actually, the logical economy does not always stop here. Often some speculative propositions are “thought up” and added to (α) with a view of shifting as many α -propositions to (β). Thus, (α) is replaced by (ω), the latter having the same properties and the same relation with the new (β) as (α) has had. The only difference is that (ω) contains some unobservable propositions, i.e., some first principles. But this does not affect the validity of the equation written above. [pp. 6, 7]

3. To sum up: *Anatomically*, theoretical science is logically ordered knowledge. A mere catalog of facts, as we say nowadays, is no more science than the materials in a lumber yard are a house. *Physiologically*, it is a continuous secretion of experimental suggestions which are tested and organically integrated into the science’s anatomy. In other words, theoretical science continuously creates new facts from old facts, but its growth is organic, not accretionary. Its anabolism is an extremely complex process which at times may even alter the anatomic structure. We call this process “explanation” even when we cry out “science does not explain anything.” *Teleologically*, theoretical science is an organism in search of new knowledge. [p. 15]

4. In place of “all sciences must imitate mechanics,” the battle cry of the scholarly army is now “no science without theory.” But the change is rather skin deep, for by “theory” is commonly understood a logical file of knowledge as exemplified by geometry and mechanics. [pp. 17-18]

5. . . . we cannot cease to admire men like Jevons and Walras, or numerous others who even in physics hurried to adopt a new viewpoint without first testing their ground. But our admiration for such unique feats does not justify persistence in a direction that trying has proved barren. Nor do we serve the interest of science by glossing over the impossibility of reducing the economic process to mechanical equations. [pp. 18-19]

6. Opposition to Walras’ and Jevons’ claim that “economics, if it is to be a science at all, must be a mathematical science,” has not failed to manifest itself. But, in my opinion, during the ensuing controversies swords have not been crossed over the crucial issue. For I believe that what social sciences, nay, all sciences need is not so much a new Galileo or a new

Newton as a new Aristotle who would prescribe new rules for handling those notions that Logic cannot deal with.

This is not an extravagant vision. For no matter how much we may preen ourselves nowadays upon our latest scientific achievements, the evolution of human thought has not come to a stop. To think that we have even approached the end is either utter arrogance or mortifying pessimism. We cannot therefore write off the possibility of striking one day upon the proper mutant idea that would lead to an anatomy of science capable of thriving equally well in natural as in social sciences. [p. 19]

7. . . . *discrete* distinction constitutes the very essence of Logic: . . . [p. 21] Since any particular real number constitutes the most elementary example of a discretely distinct concept, I propose to call any such concept *arithmomorphic*. Indeed, despite the use of the term "continuum" for the set of all real numbers, within the continuum every real number retains a *distinct individuality* in all respects identical to that of an integer within the sequence of natural numbers. The number π , for instance, is discretely distinct from any other number, be it 3.141592653589793 or 10^{100} . So is the concept of "circle" from "10¹⁰⁰-gon" or from "square," and "electron" from "proton." In Logic "is" and "is not," "belongs" and "does not belong," "some" and "all," too, are *discretely* distinct. [p. 22]

8. At a particular historical moment a nation may be both a "democracy" and a "nondemocracy," just as there is an age when a man is both "young" and "old." Biologists have lately realized that even "life" has no arithmomorphic boundary: there are some crystal-viruses that constitute a penumbra between living and dead matter. Any particular want, as I have argued along well-trodden but abandoned trails, imperceptibility slides into other wants.

It goes without saying that to the category of concepts just illustrated we cannot apply the fundamental law of Logic, the Principle of Contradiction: "B cannot be both A and non-A." On the contrary, we must accept that *in certain instances* at least, "B is both A and non-A" is the case. Since the latter principle is one cornerstone of Hegel's Dialectics, I propose to refer to the concepts that may violate the Principle of Contradiction as *dialectical*. [p. 23]

Another suggested limitation of arithmomorphic theories is that qualities cannot be usefully incorporated. Even if other difficulties were overcome, the sheer number of qualities would be too great.

9. Clearly, there is no reason why the cardinal power of all the qualities we can think of even in a simple set-up should not exceed that of the arithmetical continuum. On the contrary, as I have argued in relation to individual expectations and preferences, there are good reasons for the view that real numbers are not always sufficient for cataloguing a set of qualities. In other words, the manifold of our thoughts differs from the arithmetical continuum not only by its indivisible continuity—as I have explained in some of the preceding sections—but also by its dimensionality. As we say in mathematics, the continuum of the real number system forms only a simple infinity.

The suggestions, natural at this juncture, of using more than one real number, i.e., a vector, for labeling qualities would still not reduce quality to number. For, as set theory teaches us, no matter how many coordinates we add, no set of vectors can transcend simple infinity. [p. 39]

These views are developed in the first two chapters of the new essay. In chapters 3 and 4, "Some Object Lessons from Physics" and "Evolution versus Mechanics," various developments in physical sciences are considered along with scientists' statements on related philosophic issues and some of the author's reactions.

The discussion is interesting and sometimes provocative. I believe many readers will join me in sometimes questioning the author's interpretations, but it does not seem appropriate to try to pursue these issues now. Since I am not at all familiar with some of the contexts and have not deeply studied others my reactions of agreement and disagreement are at this state too casual to mention. In addition, these interpretations do not seem vital to the author's or readers' views toward economics. Once one foreswears, as the author seems to do in quotation 4 above, prior notions about how closely the viewpoints and theoretical apparatus of one science can usefully be copied in another, there is no compulsion to determine one's approach to his own science according to the outcome of discussions elsewhere. Study of other sciences is, of course, still important. Interesting hints, contrasts and parallels may be found. Occasional fruitful inspirations may be had, and it is to be hoped that unifying principles (as between physics and chemistry in recent decades) will sometimes emerge. However, possible relevance to another field must be critically examined.

The final chapter, "General Conclusions for the Economist," continues various threads of discussions introduced earlier. Not all of the conclusions are startling. For example, a discussion of possible significance for economics of the study of entropy concludes—

10. It is thus seen that we cannot arrive at a completely intelligible description of the economic process as long as we limit ourselves to purely physical concepts. Without the concepts of *purposive activity* and *enjoyment of life* we cannot be in the economic world. And neither of these concepts corresponds to an attribute of elementary matter or is expressible in terms of physical variables. [p. 98]

After a section on the boundaries of economics, the nature of theoretical science and the disqualifications of economics are again considered.

11. *Why Is Economics Not a Theoretical Science?* Everyone uses "theory" in multifarious senses. To wit, in one place Schumpeter uses it to mean "a box of analytical tools." But in discriminating usage, the term generally denotes a logical edifice. Or, as I have explicitly put it (Chapter One, section 4, above), theory means a logical filing of *all* extant knowledge in some particular domain such that every known proposition be either contained in the logical foundation or deducible from it. That such a filing has the unique merit of affording *comprehensibility* is a leitmotif inherited from Aristotle. However, hardly any attention has been paid to the fact that there can be no comprehensibility without the *compressibility* of extant knowledge in only a relatively few ω -propositions. If our knowledge

of a certain domain is not compressible, i.e., if its logical filing results in a very great number of ω -propositions, Aristotelian comprehensibility does not obtain. I have illustrated this point in connection with chemistry where, because of the frequency of novelty by combination, any logical foundation must contain far more numerous propositions than the β -class. For the same reason a logical foundation of chemistry would have to be continuously "under construction." A chemical theory, clearly, would serve no purpose whatsoever. The same applies with even greater force for any science concerned with evolution, for the scene of evolution is dominated by novelty. [p. 108]

The principal argument elaborated in the remainder of the section is that economic theory as we know it applies to a particular institutional setting and therefore does not have the required comprehensibility, it is not a filing of all extant knowledge. The remainder of the paper stresses the view that a critical difference between the social and natural sciences lies in the purposes served by arithmomorphic models in the two areas. Models serve didactic purposes in both areas, but in physical sciences a model is also a calculating device or accurate blueprint whereas in social science a model is best regarded as an analytical simile.

12. To illustrate now the difference between blueprint and simile, let me observe that one does not need to know electronics in order to assemble a radio apparatus he has purchased in kit form. All he needs to do is follow automatically the accompanying blueprint, which constitutes an *operational* representation by symbols of the corresponding mechanism. The fact that no economic model proper can serve as a guide to *automatic action* for the uninitiated, or even for a consummate economist, necessitates no special demonstration. Everyone is familiar with the dissatisfaction the average board member voices after each conference where some economic consultant has presented his "silly theory." Many graduate students too feel greatly frustrated to discover that, in spite of all they have heard, economics cannot supply them with a manual of banking, planning, taxation, and so forth. An economic model, being only a simile, can be a guide only for the initiated who has acquired an analytical insight through some laborious training. Economic excellence cannot dispense with "delicacy and sensitivity of touch"—call it art, if you wish. And it is only too bad if at times the economist lets himself be surpassed in this respect by the layman. The widespread view that the economist's role is to analyze alternative policies, whereas their adoption is the art of statesmanship, is no excuse. An artless analysis cannot subserve an art. [p. 117]

Although I find much that is instructive in Professor Georgescu-Roegen's discussions of particular problems and developments, I find myself in frequent disagreement with his conclusions and broad interpretations. This can in part be traced to my not accepting his rigid Aristotelian interpretation of theoretical science (quotations 11, 2, 3). Is a science not theoretical if it (temporarily we hope) has to employ several logical structures to interpret relevant observed phenomena? Is it not theoretical if its logical foundation is continuously "under construction"? Is there now or likely to be any science which really meets the author's criteria? Note that he refers several times to the current

need for a corpuscular and a wave theory in physics and, on page 30, lists important changes in physical theories.

Granted that economic theory as developed in Western industrialized countries has aspects which do not apply in other institutional settings, is this problem basically different from that of the applicability of some physical theories to other galaxies? Is this kind of lack of comprehensiveness really a disqualification in either domain?

While the role of theory in permitting a scientist to deduce new implications (tentative hypotheses whose empirical refutation would lead to a need for some theoretical reformulations) is not neglected in the new essay (e.g., the latter part of quotation 2), I believe it is underemphasized relative to the role of theory as a compact store of established knowledge. Such results as Slutsky's equation and Hicksian relations among cross elasticities follow readily from Walrasian models but apparently did not appear until such models had been analyzed for some time.

The author's use of the term, arithmomorphic, is unclear and troublesome. Statements like ". . . within the continuum every real number retains a *distinct individuality* in all respects identical to that of an integer within the sequence of natural numbers" (p. 22) and "Whatever properties the arithmetical continuum may have, its structure is still that of beads on a string, *without the string*" (p. 33), are at best confusing and if interpreted literally are false. Quotation 7 reads as though a concept is arithmomorphic if it is distinct from other concepts (among the items which are unclear is whether or not discretely distinct means anything different from distinct). If this is the intention, arithmomorphic just means well defined and there is no more reason to associate the concept with the real numbers than with any other set since nonidentical elements of any set are distinct.

In other passages (e.g., quotation 9) the term is used as though it implies other properties of the real continuum as well. If this is the intention, then one should not assume that theories need to be based entirely on arithmomorphic concepts. Mathematics provides many possible structures with varying properties in terms of which theories might be formulated. Real numbers have been predominately used (though not exclusively, e.g., integers, complex numbers, vector spaces) because, fortunately, many empirical phenomena reflect the properties of real numbers to a satisfactory approximation and because, unfortunately, many scientists are only acquainted with real numbers and a few closely related structures.

The problem of choosing appropriate structures can be illustrated by pursuing the example of quotation 9 a little further. Georgescu-Roegen notes, as seems reasonable, that in some contexts the number of qualities that an economist needs to represent may exceed the number of real numbers available, i.e., the cardinality of the continuum which he calls simple infinity. He considers the possibility of using vectors to represent the qualities and concludes, "no matter how many vectors we add, no set of vectors can transcend simple infinity." The conclusion is true only if we are restricted to vector spaces of countable dimensionality.

Consider the set of all real-valued functions defined on the unit interval.

The cardinality of this set is greater than that of the continuum and the set is a vector space. Moreover it can readily be made a metric space (also a Banach space) so a large array of mathematical results are at hand to help analyze any phenomena that can usefully be represented as vectors in such a space.

This of course, does not mean that the space is necessarily a good one to serve as a space of qualities. To judge its appropriateness one would first have to bring sufficient economic considerations to bear to say what properties are needed or desirable in a space of qualities. If no previously studied mathematical structure provided a suitable framework, the possibility of developing one could be explored. Probability theory is a good example of a branch of mathematics whose development has been partly guided and greatly stimulated by the desire to have a suitable mathematical foundation for interpreting a specific class of empirical phenomena. Of course, it may be some time before economists understand qualities well enough to determine the kind of mathematical structure needed.

Trying to develop new theories involving, when it seems promising, hitherto unutilized mathematical structures is an endeavor quite different from trying to "prescribe new rules for handling those notions that Logic cannot deal with" (quotations 6 and 8). I cannot see that the author has developed a strong case for the latter. The notions that logic cannot deal with are incompletely defined notions. We cannot do without these and ordinary parlance involves a large fraction of such terms. But the cost of including poorly defined terms in theories is confusion.

The cost of casting theories in well-defined terms is that theory represents a highly idealized reality. Choosing the aspects of reality to be reflected with some accuracy and those to be grossly simplified is a vital choice which demands all the "delicacy and sensitivity of touch" (quotation 12) that can be mustered. The latter qualities are also crucial for applying theories to a complex and only partly understood world.

In the various respects discussed above it seems to me that the positions of theories in natural sciences and in social sciences are much more alike than different. Nor can I agree that these sciences differ greatly in ability to furnish blueprints (see quotation 12). Economics engineers have furnished blueprints for such decisions as where to borrow money and how to choose an economical ration for animals. I suspect a not altogether useless blueprint for national economic stabilization policy could also be constructed. It would not work satisfactorily in all circumstances but neither does a blueprint for a radio installation. For a particularly important or novel installation scientists are usually consulted as scientists are consulted for important aspects of economic stabilization. Disagreements among economic scientists are more widely publicized but disagreements among physical scientists on both abstract and practical levels certainly exist. It would be fun to have information for making a meaningful comparison.

CLIFFORD HILDRETH

University of Minnesota

The Structure of Economic Science: Essays on Methodology. Edited by SHERMAN ROY KRUPP. Englewood Cliffs, N.J.: Prentice-Hall, 1966. Pp. vi, 282. \$7.95.

Inevitably, sixteen original essays on methodology will reflect sixteen different positions—and at least as many terminologies. I may perhaps be forgiven for interpreting them along a single broad continuum and for imposing a common (in both senses of the term) vocabulary, if it is understood in advance that violence will be done to all. The center position on the continuum proceeds by analogy to physical science: constructs are distinguished from brute reality; they are related to it by rules of correspondence; they are related among themselves in a deductive system providing inferences which are certain; ever greater generality is sought through ever higher degrees of abstraction; consistency and ability to predict are the criteria of confirmation and explanatory power. These principles are graphically reviewed by the physicist-philosopher Henry Margenau. He also defines an inductive approach, which relates empirical variables and arrives at probabilistic conclusions of limited applicability and explanatory power.

The former, "scientific" approach identifies the center of the continuum and the latter, the empiricist end. The distinction reflects much of recent controversy in economics such as the discussion emanating from the first chapter of Milton Friedman's *Essays in Positive Economics*. This, as well as several other controversies, are usefully unravelled by Martin Bronfenbrenner in an introductory review essay. He is permissive to the point of reducing significant differences of viewpoint to a matter of subjective preference. This will satisfy few, and rightly so. Fritz Machlup's paper is a specific, unrelenting attack on empiricism. Eugene Rotwein, by no means an extreme empiricist, recognizing that highly abstract systems may provide insights and first approximations and that even "descriptive" propositions represent a degree of abstraction, in the end requires that empirical verification apply to each concept directly, which is the heart of the matter. These authors and their allies have developed their basic positions elsewhere, and few readers will be further swayed by the elaborations here. I am persuaded that, as in previous confrontations, the advantage is with the centrists. Be that as it may, the latter are not home free. The strength of this collection is that it probes the other part of the continuum. This can be loosely defined as extending out from the center as empirical confirmation is held to be even less direct, possible, or passive. To that extent, theory is thought to be characterized by a greater degree of contingency, and ultimately relativism may emerge.

It is customary for the centrist position to emphasize, as do Machlup and Bronfenbrenner here, the distinction between logical and empirical validity of a theory. A "truth" value is imputed to models so long as they are consistent with their axioms. Applicability is another but a separate criterion, and, as in physical science, it is guided by the device of *ceteris paribus*. However, in physical science, when the *ceteris paribus* conditions are ultimately cancelled out, the various parts are brought together into general principles which are formidable in their scope as well as in their consistency. In this precise sense the whole possesses greater validity than its parts. Emile Grunberg is sensitive

to the plight in economics, although he remains committed to noncontingent relationships. He shows, in effect, that it is not sufficient to assert the magic words, *ceteris paribus*. Laws must "make explicit mention of all the conditions under which a particular effect is expected to occur." Because of the indefinite number of relevant variables, hypotheses in economics are subject to an "unspecified" *ceteris paribus* condition. The consequence is an "open system" in which hypotheses are not disconfirmable since failure of prediction may be due either to false hypotheses or to the failure of the values of some of the "givens" to remain in fact constant. K. E. Boulding, in his discussion of verifiability, makes the related point that random elements render the parameters of an economic system relatively unstable and thereby frustrate prediction. He believes that this may impose ultimate limits on knowledge of society but that there is a long way to go, and his own interdisciplinary labors represent one kind of attempt to firm up the parameters.

The rationale for much, although not all, of the crossing into other disciplines is sharper specification of the *ceteris paribus* conditions by expanding the scope of the theory. An alternative or additional strategy is to seek closure of the system by introducing a principle of selection which will restrict variables and relationships to those judged relevant, but which will salvage some kind of general status for the theory. (Closure as has been indicated, has a meaning more substantive than merely formal determinacy.) S. R. Krupp's typology of controversies in economics shows that such discrimination—based on time runs, problem and policy orientations, differentiated socio-economic systems, values—may be the ultimate source of conflict. Lawrence Nabers suggests that the history of economic thought, as a branch of the sociology of knowledge, needs to take such selective orientations into account in its interpretations.

Attempts to close the system by value judgments have a long history. Typically, they have taken the form of applying such judgments to individual preference schemes. Although Jerome Rothenberg marshalls the strongest possible case for a positive theory, free of value judgments, he allows for a separate normative economics. He shows that the poverty of the Paretian version has provoked a variety of formulations which are more radical from the standpoint of centrist methodology. His own work on the possibility of empirically establishing value consensus in a given society illustrates one such approach towards closure of a system so that it can provide more general results.

A philosophical underpinning for the view that statements about the mental states of others (conceived as preferences and not pleasures) are empirically confirmable is provided by R. B. Brandt. He is unclear as to how much of the analysis applies to interpersonal comparisons, but a large part does, and is a useful antidote to exaggerated purism. Although precise measurement of utility involves familiar unresolved difficulties, the ability of even ordinary language to convey empathy in some degree suggests that the problem is not one of principle. Acquiescence in Brandt's further contention that statements about individuals' preferences constitute value judgments which are confirmable by the methods of empirical science depends on one's taste for analytic philosophy. A different philosophical argument is employed by C. W.

Churchman to the effect that measurement and interpersonal comparison of utility must be possible because the "criteria of objective evidence of wants," i.e., of measurement, are created through a social process. Preferences are not merely internal givens; they are "ascribed." The presentation is terse but amounts to a devastating polemic against solipcism concerning intensities of preference.

Useful surveys dealing with method from the standpoint of mathematical economics and econometrics by W. J. Baumol and by Gerhard Tintner, special problems of aggregation for micro-macro consistency by Kelvin Lancaster, and linkages between economics and other disciplines by J. M. Buchanan and by Benjamin Ward round out the volume. The collection as a whole represents a unique dialogue on methodology, in terms of coverage of topics, variety of viewpoints, and qualifications of participants. It summarizes as well as contributes to the glacial advance of clarification in this area. Both the general economist and the addict will be served.

PETER N. VUKASIN

State University of New York at Binghamton

Modern Economics: An Introduction. By LORIE TARSHIS. Boston: Houghton Mifflin, 1967. Pp. xvi, 814. \$8.95.

Exactly 20 years after publication of his pathbreaking introductory text, *The Elements of Economics* (Boston, 1947) emphasizing national income and employment analysis, Professor Tarshis now provides a new textbook for the beginning course. Or if not entirely new, then at least a modern revision of his earlier work.

Modern Economics is a competent and conventional book by a respected economist, and it will surely find an appreciative audience of students and professors. It is not, however, another pathbreaker; nor does it claim to be. The book is traditional in approach, treatment, and style. "Alas, a moment's reflection [discloses that our society] has not managed to banish economic want and do away with scarcity," p. 59; "The business firm in our economy embraces both the little boy who shines shoes" [and AT&T, p. 45]. It is a historical, not highly mathematical, not more difficult nor less readable than average, has the standard 800 pages, and contains idiosyncracies of style and notation that will prove inconvenient to experienced teachers who dislike molding their course entirely to a textbook (e.g., pp. 13ff, classification of productive factors; p. 431, GNP multiplier represented by $M = 1/1-R$; p. 313, inelastic demand curve for money). In Tarshis' own view, it is one more contribution to the "proliferation of brands" in the textbook market, offering "some things that are new and others that are at least put in new ways." One can anticipate that the availability of this book may make the selection of a "Principles" text harder for some teachers of the course, though it won't make the task easier for many.

Modern Economics is divided into seven sections, plus a very brief Preface and Epilogue (in which students are comforted at journey's end with the author's guess that "as long as we continue trying to keep the economy competitive and to improve budgeting procedures within firms and government,

we can be reasonably content with the patterns of the [economy's] output." This organization reflects emphasis on four economic questions: (1) *How much output* will the economy produce? (national income analysis—33 per cent of the book); (2) *What kinds of output?* (microeconomic theory, with heavy emphasis on the business firm—27 per cent); (3) *To whom will the output go?* (distribution, mostly functional—8 per cent); and (4) *How much output will the economy produce over time?* (growth—7 per cent). The other three sections provide an Overview of the U.S. Economy (7 per cent) and treat the separate topics of Money and Banking (6 per cent) and International Economic Relations (11 per cent).

Section One opens with a discursive Introduction that seems longer than its nine pages, owing to an unattractive typography, only the first of several unfortunate mechanical features of the book—including pastel subheadings, poor indexing, superfluous digits and ciphers in statistical tables (pp. 34, 690), some inept graphics (pp. 22, 401), and inconvenient numbering of chapters (by individual section rather than 1-42 for the entire book). The first three chapters provide a sketch of the U.S. economy and the business firm, with half a dozen pages on government.

Section Two contains 12 chapters on standard microeconomics with industry applications. The treatment is relatively thorough (no indifference curves), highly skilled, and in places novel (Ch. II-3, "Supply Under Strong Competition" and Ch. II-7, "Mark-up Pricing and Marginal Pricing").

Section Three concisely treats the financial sector, with some emphasis on near-money and non-bank financial institutions. Section Four consists of 13 chapters on "The Size of the Nation's Output" with special chapters on Inflation, Debt, and Automation. Section Five includes income distribution, with attention devoted almost exclusively to functional distribution (since this "is what primarily interests the economist") and labor market structure. Tarshis dismisses the need for any special treatment of poverty, pointing out (p. xi) that "after all, what is economics about if it is not about poverty?" Section Six deals with "the incredible chaos of opinion" on growth, both for the "have-not nations" (poverty does receive some attention here) and the advanced economies, drawing heavily on Denison's findings for the United States. The final section provides a thoughtful treatment of "The United States Economy in the World Context," with sharp focus on balance-of-payments accounting procedures and on policies for restoring equilibrium.

It would appear that the opportunity cost (one of the many concepts missing from the index and neglected in the text) of the author's expanded treatment of the international sector is a regrettable neglect of income distribution and public finance. In speculating on what it is that students will need to know 5 or 10 or 15 years hence in order to keep up with current economic events, we might well agree with Tarshis that international economics clearly demands greater attention. On the other hand poverty, resource development, and the public sector are not likely to shrink in importance in the coming decade, and widespread public understanding in these areas is still sorely lacking.

One final note: Although Tarshis demonstrates awareness of and sensitivity to the subject of values and policy, he nevertheless avoids any direct confron-

tation with the problem of valuing. This may prove disappointing to serious students, who are (in the author's words) "full of curiosity and energy, skeptical, able, and concerned." Increasingly today's students are demanding that economics, along with other social sciences, provide insight and analytical skills that are immediately relevant and operationally useful in seeking out solutions to real socio-economic problems, like poverty and urban decay. They are impatient with the familiar position reiterated (pp. 595f.) by Tarshis: "Luckily for the economist, the boundaries of his subject are such that these [value] questions are left to others . . . [His] concern must be to serve neither as an apologist for nor as a critic of 'the system'; these are different roles to be played perhaps by a lawyer, or a politician, or a journalist." Idealistically, today's students look to economics and social science if not for answers then for methods of finding answers, based on disciplined reasoning and hard evidence, in place of unsatisfactory methods and economic-policy judgments of the lawyers, politicians, and journalists.

ROBERT L. DARCY

Ohio University

Growth and the Economy: Principles of Economics. By DAVID MCCORD WRIGHT. New York: Charles Scribner's Sons, 1954. Pp. xii, 398. Paper, \$5.25.

Professor Wright's Principles text is less than half the length of the heavy volumes which dominate the market. Brevity has been achieved not only at the expense of much historical and institutional information but also at the sacrifice of much of the principles of economic analysis generally demanded of students in introductory courses nowadays. For this reason the book can hardly serve for the standard two-term course. It does not provide the hard theoretical skeleton which could be fleshed out with supplementary readings.

The book is extremely uneven both with regard to quality of analysis and of style. Its theme, from the first chapter to the last, is that "growth comes through change and causes change. As output expands, the pattern of wants constantly changes, and also the pattern of production." In expounding his views on the prerequisites for maintaining a social system's capacity to generate growth and adapt to change the author is often interesting as well as provocative and sometimes eloquent. But the presentation of standard static price theory (Chs. 6-11) and of income-expenditure theory (Chs. 19, 20) is perfunctory. Here the theme of ever-ongoing change takes the form of repetitive reminders that the propositions derived are "theoretical" and that the *ceteris paribus* assumptions seldom hold. In addition, the author is satisfied with giving only a "general idea" of many important concepts and functional relationships. As a consequence, the student can hardly help but be left with the feeling that in economic analysis "anything may happen."

Production methods must change with growth "for there is (a) technical expression, 'the law of diminishing returns,' which says that in an unchanged technical environment growth becomes progressively more difficult" (p. 10). The proposition that "the pattern of want will change as output changes," the author seeks to base on differences in the price elasticities of demand for

different goods, while openly admitting that the argument "violates the *ceteris paribus* assumption of the individual demand curve" (p. 69). Getting into immediate difficulties, he then leaves the student to his own devices: "a very little imagination will show that some consumption experts, or market analysts, will use three-dimensional calculations of income, price, and sales change, but we do not enter on such complications here." In this case, the student's imagination has little to work with since the book does not introduce him to indifference curve analysis. The first three parts (143 pages) contain many other exceedingly loose formulations, e.g., on the Law of Variable Proportions (pp. 79-80), on the relationships between Marginal and Average Product (p. 81) and between Supply Curves and Cost Curves (pp. 87-88), and on the definition of the Marginal Efficiency of Capital (p. 105). There are few diagrams and algebra is shunned altogether. In its stead, the term "proportional" does heavy duty, being used to denote equality of ratios (p. 62), elasticity (p. 66), and partial derivative (p. 80).

The five chapters on National Income Measurements and Money, Banking and Credit Control generally do a creditable job within the short space allotted, although the first of them confuses matters by twice referring to the basic accounting convention as the "equality of prices and incomes." The pride of place given to the idea of ever-ongoing change next dictates that business cycle theories be discussed before the student has been introduced to the theory of income determination. In Chapter 17, Professor Wright has his heart in the work—it deals exclusively with "over-investment" and is probably the best in the book. Remaining cycle-theories are given one chapter and here the author has to discuss the interaction of multiplier and accelerator while the reader has two chapters to go before encountering the explanation of the multiplier. Even one who shares some of the author's skepticism of the simple income-expenditure model must find his 27-page sketch entirely too cursory. From the proposition that "we have full employment when the 'inducement to invest' and the 'propensity to consume,' taken together, add up to full employment" (p. 222), the student is taken post-haste to the implicit advice to forget the whole thing: in the real world, the multiplier "is almost wholly unpredictable"; the marginal propensity to consume "might rise or it might fall" (p. 241).

The 100-page Part IV has three chapters on International Economics, two on Government and Business, two on Unions, and one on Comparative Systems. The first five of these, in particular, are generally well written, but annoying signs of questionable craftsmanship continue to occur. (Why does the Bibliography advise the student interested in International Finance and Trade Policy to consult *International Economic Papers*, 1951 to date?) In the concluding chapter on Stabilization Policy, a variety of policy measures to combat inflation or deflation is catalogued, but there are arguments both for and against all of them, and the discussion is totally inconclusive. Three times within as many pages (pp. 354-56), the author promises to come back to a fuller appraisal later, but, in fact, the issues in question never reappear.

Teachers of introductory courses have to struggle with the tendency of many students to quit when they "feel" they understand the readings "in a

general sort of way." In this struggle, Professor Wright has all too often taken the side of the students.

**Price and Allocation Theory; Income and Employment Theory;
Related Empirical Studies: History of Economic Thought**

Industrial Production Models—A Theoretical Study. By SVEN DANØ. New York: Springer-Verlag, 1966. Pp. viii, 220. \$9.75.

The development of mathematical programming in the postwar period exercised a strong influence on the theory of production. For the first time, systematic treatment of cases involving discontinuous factor substitution became possible, and the way was opened for reinterpretation of the traditional neo-classical model. Extensive discussion in the literature has made the new themes familiar, but Professor Danø's excellent book is the first text to provide a really comprehensive and integrated exposition of the separate strands of thought on production models. By examining the formal properties of the leading types of production functions used in microeconomic theory, and contrasting the differences among them, Danø is able to give valuable perspective to the field. What emerges is a clear statement of how the older marginal analysis of the firm compares with that of linear programming, and how the modern Kuhn-Tucker generalization of marginalism relates to both these basic cases.

Because mathematical interest is on constrained systems, coverage of the book is limited to short-run analysis. The standard setting envisioned for production is a given manufacturing plant in which variable factors cooperate with fixed capital equipment. All the models considered are timeless, or mono-periodic, and no attempt is made to deal with the problems of investment, replacement, production scheduling, inventory management, or similar difficulties associated with the operation of an ongoing productive unit. Still further simplification is obtained by assuming the existence of a competitive universe; each firm is taken to be a short-run profit maximizer shaping its actions in the light of specified market prices for inputs and outputs. Of course, this specialized framework is adopted merely as a matter of convenience, and has good justification. The book's primary purpose is to explain alternate formulations of the production function, not provide a full-fledged theory of the firm. Thus, the derivation of optimality conditions for firms facing different market structures and following complex behavioral patterns can legitimately be left to the reader.

Within the limits imposed by assumptions, the discussion shows sensitivity in relating the various abstract models to the actual circumstances of production. There is no tendency to deal lightly with fundamental concepts and definitions, and then hurry on to the purely formal development of the models. Rather, a nice balance exists between economic interpretation and mathematical exposition. At times, one might wish for somewhat more information on

the state of empirical research so that a feeling for the probable "shapes" of the functions could be obtained. For example, it would be interesting to know what elasticities of substitution can be expected for isoquants derived from an individual technical process, or what internal structure a multi-variable production function tends to possess, and so on. However these are questions to which unequivocal answers are not easily forthcoming, and Danø is only conforming to a great tradition by not giving too much attention to such factual matters in a theoretical treatise.

To begin the systematic study of how different technological restrictions influence the possibilities for economic choice, Danø introduces the elementary case of fixed proportions. This simple construction affords a convenient way to approach the concept of shadow pricing and leads logically to the linear programming model of the firm. Discussion of the latter is quite adequate, but sticks to essentials and is conducted largely in terms of numerical examples rather than matrix algebra. Supplementing the work of the chapter is a useful appendix on the simplex criterion. In general, the material offered is lucid and readable without sacrificing substance to ease of presentation.

Chapters IV-VII contain a polished statement of marginalist theory—in its traditional and modern forms. Explanation of the respective single-product models proceeds with deliberation and few, if any, topics of importance escape notice. Emphasis here is, of course, on cases which assume inputs are smoothly substitutable for one another in production; however, the functions studied include both those where all inputs are mutual substitutes, and those where some inputs are substitutes and others are not (i.e., product and factor "shadows"). Standard optimization problems are examined in relation to the different types of production models presented. Of particular interest is the contrast drawn between the conventional neoclassical model, based on indivisibility of the fixed factor, and the newer approach which recognizes non-negativity requirements for the inputs and the possibility of variable utilization of plant capacity. Quite apart from economic arguments, the formal discussion makes clear that once the procedures are established for dealing with problems of maximization (or minimization) subject to inequality constraints, it is a natural step to question the indivisibility assumption and the U shaped marginal cost curve. In this area, as elsewhere, the commentary of the chapter is strengthened by detailed appendices covering the essential mathematics of constrained systems and homogeneous production functions.

The remaining chapters extend the basic theory to take account of such things as: variation in product quality, the relationship of individual process functions to the plant production function and, finally, multi-product models. Many of the concepts here are especially useful because they relate to areas of production research which have received too little attention in the past. Exposition conforms to the general standards of the book; the presentation is rigorous and tightly organized. Mathematical treatment, which involves elementary calculus, is invariably deft so that even familiar demonstrations take on new interest.

It is difficult to be critical of Professor Danø's perceptive survey of short-run production theory. The work is obviously of high quality and meets the

need for an authoritative text outlining the modern position. Of course, one can disagree with the book on matters of emphasis, or question the omission of particular topics; for example, it seems regrettable that there is no mention of learning and the adaptive production function. However, these problems are essentially minor. The one important criticism that can be made concerns the book's failure to explain, at least in general terms, the relationship between a static model and a dynamic economic system. Preoccupation with rigidly circumscribed short-run analysis means that the theory of production is wholly separated from the theory of investment—yet adequate understanding of instantaneous production decisions almost always depends on knowledge of the long-term optimization plan.

EIRIK G. FURUBOTN

State University of New York at Binghamton

Théorie générale du capital, de la croissance, et des fluctuations. By A. COTTA. Paris: Dunod, 1967. Pp. 430.

In this review I would like to call to the attention of American readers a novel and most interesting work just published in Paris by one of the ablest of the new generation of French economists. Cotta attempts to formulate a general theory of economic fluctuation and economic growth. In so doing he departs, and I think goes beyond, the Keynesian paradigm by focusing in a particular way on the role of "capital." What Cotta means by "capital" is, however, a world removed from the Böhm-Bawerkian notion or from the National Bureau datum. Cotta, rather, is concerned to explore the relevancies of virtually every form of real or financial stock and accumulation, including the funds and securities representing financial "wealth," including all the goods in store and inventory and in personal possession intended for private consumption, including tools and materials durable and nondurable, to be used in the processes of production, and finally (and especially) including the accumulation of "knowledge." These accumulations are understood, and are carefully and elegantly analyzed both as the primary objectives of economic endeavor and as the major constraints upon economic activity.

Cotta's book deserves to be quickly translated and made available in English. One hopes that it soon will be. Meantime, it should not be neglected by those who have the competence to study it in the original.

ROBERT A. SOLO

Michigan State University

Microeconomic Theory. By C. E. FERGUSON. Homewood, Ill.: Richard Irwin, 1966. Pp. xiv, 439. \$8.00.

In addition to the traditional treatment of consumption, production, the firm, and factor markets, Professor Ferguson includes chapters on general equilibrium theory and welfare economics. To me, this is a desirable extension of intermediate price theory. Other innovations are a brief discussion of game theory and technical change, an early presentation of Edgeworth boxes, and some comments upon recent empirical studies in microeconomic theory. Expla-

nations are generally lucid, and many interesting exercises appear at the end of chapters and in an appendix [by] Fritz Machlup. The references are extensive although not always up to date, and on the whole the presentation is of a scholarly nature.

With regard to particular topics, I like the treatment of the following: (1) The Sweezy theory of oligopoly is exposed as vacuous (pp. 277-78). (2) There is a good discussion of the dependence of factor demands on the own factor price and the own product price. I hope that future editions will incorporate the analysis of the dependence of factor demand on the other factor prices [7, Ch. 6] [8] [10] [15]. Also, Ferguson uses the property that an increase in the use of one factor increases the productivity of another. This is not obviously derivable from other properties (e.g., diminishing returns) and often must be treated as an axiom [2]. (3) There is a substantial section on cartels and price leadership (pp. 286-94). (4) There is no sign of capitulation to non-neoclassical theories of the firm, such as "satisficing." (5) The survey of utility theory is a good one (pp. 11-24), although an exposition of Occam's razor might have made clearer the difference between cardinalists like Jeremy Bentham and "quasi-cardinalists" like every economist who maximizes a utility function.

Unfortunately, the book suffers from several flaws. There are both sins of omission and sins of commission. Many of these are shared by most other intermediate (and elementary) textbooks, but this makes them no less annoying. Some appear below.

1. As in most texts, with the notable exception of Stigler [18], we are told that whenever the long-run average cost curve is U shaped, the long run equilibrium of the industry is at the minimum point of that U (pp. 213-14). But we are reminded that this is not so if the long-run average costs are increasing over the whole range of output (p. 217). Evidently, as the bottom of the U tends to the zero output, long-run industry output tends to zero, but once the limit is reached, the industry is released from the bounds of long-run equilibrium. Are we to believe that an industry with the slightest indivisibility so as to have a U shaped cost curve with a minimum at say $1/1,000,000$ of a milligram is relegated to that output in the long run?

The source of the difficulty is easy to discover. The assumption is made that new firms will enter until they drive the profits down to zero. Evidently, there is a virtually infinite source of entrepreneurial talent. This analysis is objectionable on economic grounds. First, if knowledge is in fact unlimited, as in the case of an unlimited supply of entrepreneurs, what then is the source of diminishing returns to the industry? Why should average cost curves be U shaped to begin with? (Here, one is involved in Clapham's empty boxes [13] [17] [5].) Second, one would expect per capita output to increase over time. The entrepreneurial role is played by people and, therefore, the ratio of output to entrepreneurial talent grows steadily. Entrepreneurship becomes a scarce "factor" and requires a rent, namely, a positive profit from firms. The only reason this factor is not treated like others is that knowledge is attached to indivisible units, namely people.

2. We are told that the going market price is the one where supply equals

demand (Ch. 9). As a matter of fact, a market is not always in equilibrium and the tendency of price to equal the equilibrium price is dependent upon a dynamic adjustment system (Samuelson [16, p. 68, pp. 480-86]). If an equilibrium price is not stable for the dynamic system, then that price does not represent the going price.

3. Although a long-run theory of cost appears, no mention is made of the very significant costs of construction and organization of new plant and equipment, which limits the rate of expansion of the firm. Ferguson's approach is the traditional one of Viner (pp. 175-84), which assumes that set-up costs will not change over time so that the firm expands at the maximum rate possible. To the contrary, a major part of the investment decision of firms is concerned with the pace of expansion (Eisner and Strotz [4]). The solution to such problems determines the set-up costs incurred and therefore the level of a long-run marginal cost curve. Possible analytical techniques to use are dynamic programming and the calculus of variations.

4. Ferguson's presentation of welfare economics is limited to the Bergson approach. He does not enumerate the fundamental classical theorems (Arrow [1] and Debreu [3]): (a) A competitive equilibrium is Pareto optimal, and (b) Any Pareto optimum can be attained by a competitive equilibrium with an appropriate redistribution of wealth. Incidentally, these are easily illustrated by use of the Edgeworth box (Newman [12]).

5. Similarly, his treatment of general equilibrium theory suffers from a lack of reference to modern developments.

No longer is the number of equations said to be sufficient to insure the existence of equilibrium, but the distinct impression is left that it is necessary (pp. 361-62). This is not the case: linear equation systems with n unknowns and m equations $n > m$, normally have solutions, provided the equations are linearly independent. Even if the number of equations exceeds the number of unknowns, a system of linear equations may have solutions. What can be shown is that if the number of variables equals the number of equations, if the matrix of partial derivatives has linearly independent rows, and if one equilibrium exists, then there are no others nearby; the equilibrium, if it exists, is "locally" unique (up to a multiplicative constant). Again, the existence of competitive equilibrium can be constructed for the Edgeworth box. Ferguson's figure 4.2.2 (p. 63) is all that is needed for the purpose.¹

6. In his treatment of production, he states that the firm will never choose to produce in region I, where marginal costs are falling (pp. 121-22). He does not warn the reader that he intends only to say that the competitive firm will never choose such a production. This becomes clear only later when a counter example is illustrated for a monopolist (figure 104.7(b), p. 239). A more substantial objection is that the reader is told that a U shaped cost curve is com-

¹First, observe that, from an initial position, a line segment to the upper right-hand origin is below the line tangent to the indifference curve through the origin. Second, the line segment and the tangent lines vary continuously along the contract curve to the lower left-hand origin, where the line segment lies above the tangent line. Somewhere between, the line segment coincides with the tangent line. This gives a competitive consumption; the price system is derived by taking the coordinates of a vector tangent to the tangent line.

patible with pure competition without being warned that in this case, competitive equilibrium may not exist, even at a zero level of output [9, pp. 49-50] and [14, pp. 170-72].

7. In his presentation of elasticity of market demand (pp. 77-89), Ferguson omits the fact that market demand elasticity is the weighted average of individual consumer demand elasticities [18, pp. 42-43].

8. Ferguson ignores the Nash [11] and Zeuthen (Harsanyi [6]) approaches to bargaining games, whereupon he states unequivocally that the consensus on game theory is that it is "more relevant to the study of specific business problems than to general theory" (pp. 278-79).

9. Also, Ferguson declares that the indeterminacy of bilateral monopoly is due to the fact that economics does not contain all the aspects of bargaining skills and personal characteristics necessary to determine the outcome (p. 248). Equally well, it could be argued that the problem is simply not well defined, and if various kinds of bilateral monopoly were specified, then a solution could be found. In my opinion, the Nash solution applies to one of these varieties, namely where bargaining leads to an enforceable contract.

10. Ferguson writes that "in almost all cases the income effect is positive" (p. 49). Such a statement requires empirical reference and/or logical justification.

11. There appears an uncritical presentation of monopolistic competition (Ch. 11). An alternative viewpoint is given by Stigler [19].

12. After an extensive discussion of the distinction between social and private costs (pp. 163-65), Ferguson might have pointed out that under some circumstances they are equal (e.g., competitive equilibrium with the "proper" income distribution under convex preferences and production possibilities).

I would recommend the text for classroom use if and only if the teacher supplements the text to make these reservations.

Macroeconomic Analysis. By E. SHAPIRO. New York: Harcourt, Brace and World, 1966. Pp. xx, 618. \$8.95.

Macroeconomic Analysis is an intermediate undergraduate text that utilizes the orthodox Keynesian "elasticity pessimistic" models complete with liquidity trap as the vehicles for discussion of aggregate income determination.

The menu is rather standard fare. With a few transpositions of chapter headings, the table of contents could easily be mistaken for that of Ackley or Dernburg and McDougall. The relative allocation of space to subject matter is about the same as that in Dernburg and McDougall with one exception. Shapiro devotes a relatively large number of pages—124—to National Income Accounting. He works up from a two-sector through a four-sector economy before discussing the U.S. accounts. Whether this is good or bad depends upon one's point of view. I do not happen to find the rules of income accounting particularly fascinating, and would prefer merely to have them stated so they can be memorized if necessary and ignored if not. Shapiro's purpose in all this is, of course, to enable the student to relate the later elaboration of investment, government, and consumption functions more directly to their real world counterparts in the accounting system.

With some exceptions, Shapiro does a rather good job of developing the standard Keynesian model with its IS-LM functions. The virtues and defects of this type of model have been amply presented elsewhere so I shall deal with only Shapiro's treatment of the system.

His discussion of the consumption function includes a comprehensive presentation of empirical findings related to consumption but is theoretically rather weak in that he relies almost exclusively on the Duesenberry thesis of "relative" versus "absolute" income levels in explaining the slopes and shifts

of various consumption functions. He completely ignores, except for one brief footnote, the intrinsically more interesting and theoretically more important permanent income hypotheses of Friedman and Modigliani and Brumberg.

In reading the section on the demand for money, I could not help but wonder why it seems to be necessary to continue perpetuating for undergraduates the idea that the demand for money (defined as means of payment) can have any rational basis other than for transactions. There are numerous riskless ways of holding assets that yield a positive rate of return and are completely liquid. The only reason why a person should hold cash instead of one of these assets is that there is some probability he will be making a payment in the near future and the cost of converting from cash to asset to cash is greater than to return over the holding period.

The speculative demand, in particular, is a rare animal to conjure up. An individual can always hold time deposits, savings and loan shares, or short-term bills and still speculate against rising interest rates. The only important entity in the economic system that might conceivably have a "speculative demand" is the banking system. If a bank's only alternatives were excess reserves and long-term bonds (because of shortage of supply of short-term notes or loans) it could conceivably choose the former. But excess reserves are not part of the money supply and therefore demand for them cannot legitimately be included as part of the demand for money. Shapiro's discussion of "idle" deposits versus "active" deposits in commercial banks is in much the same vein. Again, if the only logical reason for holding demand deposits at all is to take care of current or expected transactions, then they all must be considered "active."

Shapiro is rather critical of monetary policy for the usual reasons, i.e., that there are all kinds of "slippages" through adjustments in velocity and through the operations of nonbank financial intermediaries. The argument that results implies that the effectiveness of monetary policy as a function of the strength of application is apparently a step function. Either it is too gentle to do any good because of "slippages" or if it is tough enough to overcome these private adjustment mechanisms it is disruptive and destabilizing. There is apparently nothing in-between that might approximate a correct policy. The existence of this kind of function is yet to be proved and lacks somewhat in logic.

There are legitimate arguments against relying too heavily on monetary policy because of lags and the difficulty of forecasting and so on but, given the present legislative/executive nexus that makes spending and taxing decisions, these same arguments are applicable to fiscal policy. It would, therefore, seem rational to give at least equal weights to the two.

Overall, the book is well written. It contains many numerical examples that are for the most part useful. The book's greatest strength is its comprehensiveness. The major general weakness is the lack of an agnostic point of view that would permit genuine critical analysis of the models and systems presented. In spite of this (or perhaps because of it) it is likely to prove to be a popular book. I would rank it behind Dernberg and McDougall and Ackley, but probably ahead of other texts in the area as a teaching aid.

WILLIAM F. BEAZER

University of Virginia

Elementary Aggregate Economics. By HOWARD J. SHERMAN. New York: Appleton-Century-Crofts, 1966. Pp. vii, 249. \$2.95.

Public commentary on economics problems usually emphasizes certain slogans familiar to many and understood by few. In recent years, the "new economics" is the title given in popular publications to any discussion of national economic policy. Reflecting this vogue, several books on macroeconomics have appeared recently with the purpose of explaining in a nontechnical manner what the analysis means.

Professor Sherman's book is designed to supplement the elementary economics text or to be used as one of a series of readings in a corresponding course. With the purpose of helping the elementary student to understand "the important economic issues facing all citizens," he has organized the book around three issues: continuing unemployment and business cycles, inflation due to monopoly power, and growth in developed and underdeveloped countries. The approach and contents closely resemble an earlier book by Sherman, *Introduction to the Economics of Growth, Unemployment and Inflation*, except for the addition of certain elementary subjects such as how banks create money.

The strength of this well-written book is the discussion of business cycles in Chapters 2 to 6. Sherman presents an excellent review of the historical development of business cycle theory both before and after Keynes. In addition to a satisfactory presentation of Keynesian analysis, he discusses how it differed from the classical position and Say's Law. Utilizing modern national income terminology, Sherman reviews the work of several eminent economists including Mitchell, Schumpeter, Hicks, J. M. Clark, Hayek, Haberler, Hawtrey, Robertson, and Duesenberry. His emphasis in this part is with the theoretical causes of business cycles rather than the various policy proposals made to solve them, although the latter might have been of interest to many students. He does discuss, later in the book, the postwar debate among economists over appropriate policies to achieve economic stability.

The problem of inflation is the main subject of Chapter 7 with emphasis on the effects of oligopolistic concentration in industry. The approach is unorthodox regarding the usual elementary treatment of causes of inflation, and would be useful in explaining the view that wage-price guidelines are necessary to prevent inflation during a time of expansionary policies. Sherman argues that larger firms have a more stable profit rate, and that the effect of increased concentration of output has been to decrease the cyclical instability of profit margins in certain industries. He does not discuss, however, union influence in oligopolistic industries although he briefly discusses the general effects of unions in other chapters.

The discussion of growth in developed and underdeveloped countries is adequately analyzed in two chapters, although one might desire a more detailed study of the experience of the USSR which Sherman presents as a case study.

The final two chapters contain a discussion of monetary and fiscal policies in elementary detail and, as is true in many elementary textbooks, offers a too brief evaluation of them in regards to historical experience. For example, in discussing discretionary fiscal policy he refers to the "relatively minor prob-

lems of economic forecasting and administrative flexibility," a view difficult to accept when one examines nothing more than the debate on whether taxes should have been increased in 1966.

In summary, I would recommend this book as a supplement to an undergraduate course studying business cycle theory. I doubt that it would be more useful than Sherman's earlier book in supplementing the typical principles text used in the introductory course which was his original purpose. Its discussion of our banking system, monetary policy, and fiscal and budgetary policy is sketchy compared to that in the better principles' texts, omitting such subjects as our experience with monetary policy, problems of the public debt, and possible conflicts between monetary and fiscal policies. If these subjects, plus a more detailed analysis of the qualitative problem of unemployment, had been discussed with the same clarity and depth as that of business cycles, I believe the book would have been a more useful supplement to existing texts. However, if the book is selected for its strong features, I consider it superior to most elementary macroeconomics books now on the market.

ROBERT S. JOHNSON

University of Virginia

Economic History; Economic Development; National Economies

Accelerating Development: The Necessity and the Means. By LAUCHLIN CURRIE. New York: McGraw-Hill, 1966. Pp. xiv, 255. \$7.50.

After a distinguished academic and government career in the United States during the 1930s and in wartime, Lauchlin Currie went to Colombia in 1949 to head the first general country survey mission assembled by the World Bank. Fighting the brain drain in his own fashion, he stayed on in Colombia in a succession of roles: as adviser, businessman, rancher, and finally again as adviser and teacher. *Accelerating Development* is the result of this exceptionally long and varied exposure of a "Northern"-trained economist to the problems of one particular "Southern" country.

The book has many faults. It is disorganized, poorly written, repetitious and four of five of its 15 chapters—mainly those where Currie recapitulates and disputes the notions of his colleagues—could have been omitted without loss. Moreover, those who look to the book for the insights the author must surely have gathered on political and cultural factors bearing on economic progress will be disappointed: while Currie says that it is "absolutely essential" to take such factors into account in framing development policies his observations on the Colombian scene or national character are remarkably uninteresting as well as dubious ("The Colombians are prone to compromise, to avoid conflicts on principles and to improvise in economic matters" p. 7).

Nevertheless, it would be a pity if these defects were to keep students of economic development from having a serious look at Currie's message. For this is, above all, a book with a message which I shall now attempt to summarize.

The aim of economic development must be to assure a minimum standard of living to the poorer half of the population. This poorer half lives today

overwhelmingly in the countryside as subsistence farmers. Investment in agriculture would only make the situation of these people worse because of prevailing low income and price elasticities of demand for food, and agrarian reform would mainly serve to tie them more securely to their misery. The only way out is to transfer large numbers of people from the countryside to the cities and to provide them with productive employment there. To do this is less different from depression economics than one might think: (a) because there exists a good deal of unutilized capacity in mass consumption industries, especially if full-capacity operation is defined as round-the-clock operation in three shifts; (b) because technical advances in tropical agriculture have increasingly become available and will be more widely introduced as soon as the "man with the hoe" stops competing with the commercial farmer using tractors and fertilizer. In spite of these favorable factors, the accelerated transfer (and employment) of people from the country into the cities implicit in Currie's "breakthrough plan" requires acts of economic policy akin to wartime controls. If undue inflationary and balance of payments pressures are to be avoided, the structure of production of the country must be radically reoriented from catering to the rich and the middle classes to providing housing, public services, and wage goods for the new city dwellers; and since the tax instrument is most imperfect in countries like Colombia, resources presently misapplied must be released through a battery of mandatory controls over imports, building licenses, bank lending, and so on.

Currie gives only scattered "illustrative" indications about the size of his breakthrough plan. At one point he talks about a country with half of its labor force in agriculture and surmises that during each year of the plan the whole natural increase of about 3 per cent *plus* an additional 3 per cent of the work force in agriculture might be transferred to nonagricultural pursuits. Considering present trends, this would mean almost a doubling of the current high rate of urbanization of Latin America. Further, although the term "breakthrough" and the frequently invoked wartime analogy would make one think that the contemplated period would last a few years at most, we are told at the end of the book that the breakthrough could be considered accomplished only when the agricultural labor force constitutes no more than 10 per cent of the total, when the rate of population growth has fallen to one per cent or less, and when "basic equality of income, consumption and opportunity prevails" (p. 244). In other words, the emergency controls advocated by Currie must remain in place and function at peak efficiency for at least a generation!

In spite of such incongruities, Currie's prescriptions reflect a commendable desire to tackle the present situation in the developing countries with the means at hand instead of waiting for some *deus ex machina*—be it large-scale foreign aid, improved terms of trade, an interregional common market, or revolution. With his thorough experience in depression economics, he has correctly perceived certain characteristics of semi-industrialized developing countries like Colombia, such as disguised unemployment combined with unutilized capacity in consumer goods and construction industries, which make Keynesian remedies applicable *provided* either limited inflation is tolerated or income

is effectively redistributed or controls are enforced. Brazil in the 1950s and Cuba during the first two years of the Revolution are illustrations of the first and second provisos, respectively, while Currie is making a strong plea for trying out the third.

What seems hardest to accept is the insistence that not only land reform, but almost any allocation of resources for agricultural growth is to be avoided and the correlative assurance that the supply of agricultural output is highly elastic. While the orthodox, alarm-ringing FAO line on this subject may be subject to doubt, Currie merely asserts the opposite point of view and does not pay any attention to the evidence of inadequate growth in agricultural production implicit in recurring relative rises of food prices. He dismisses the need for agrarian reform in Colombia with the simple assertion that "the progressive farmers are generally large, and the small farmers are stagnating or retrogressing" (p. 163) in that country. It does not seem to have occurred to him that the first part of this sentence is perfectly compatible with the statement "the large farmers are *not* generally progressive"—and therefore with the need for land reform. Currie's apparent belief that in agriculture size is closely correlated with productivity is strangely uninformed.

The second part of the book is a detailed description of how the "break-through plan" would operate in Colombia. It contains interesting computations of the population that could be released from agriculture on certain assumptions about widespread "technification," i.e., by assuming that yields per employed person will rise to levels which have been reached by efficient farmers—a novel way of estimating disguised rural unemployment. These calculations were made in the early 1960s when Currie first put forward his "break-through plan," then known as "Operation Colombia." The greatest value of these proposals has been that they have led to a lively public discussion and even to some empirical research of which only a small part is to be found in the book. It is to be regretted, for example, that the information which was collected on underutilized capacity in the manufacturing and construction industries was not included.

ALBERT O. HIRSCHMAN

Harvard University

The First Industrial Revolution. By PHYLLIS DEANE. New York: Cambridge University Press, 1965. Pp. viii, 295. \$8.00; paper, \$2.95.

This is a disappointing book, adding little to the author's important work with W. A. Cole (*British Economic Growth, 1688-1959*), which was novel in scope and method. The present book is a useful, up-to-date, teaching- and learning-aid for lecturers and students; its scope is comprehensive and there are the beginnings in it for any conceivable lecture or essay about the industrial revolution. It is already in wide use, both because of its subject matter and also because of its author's prestige, but is altogether thinner than Miss Deane's earlier volume, and, moreover, often reads like a summary of it. As a shortish book, it does not rival, either in elegance or understanding, T. S. Ashton's *The Industrial Revolution* of 1948. As a quarry of information, it is

patchy. Most surprising of all, it is conventional in method; there is little in it of "new" or quantitative economic history; few statistics and not much theory. In spite of Miss Deane's claim in the Preface that she draws heavily on "economic and social historians who have been looking at the past through development spectacles," and that English industrialization has "a special relevance" to countries "currently finding it difficult to begin or to sustain a process of industrialisation," neither *economic growth* nor *underdevelopment* figure prominently in the subsequent text. Perhaps the explanation lies in the character of the book as "a course of lectures given for undergraduates"? Hence the sixteen neat chapters (two chapters a week for one term, or one a week for two terms, chapters of near-equal length—average 17 pages—and consisting of an hour's lecturing), each consisting mainly of a very general selection of information from well-known, usually secondary, sources. Perhaps this is the role of the Cambridge lecture, but the result in print is a series of bald and indecisive summaries which together do not give a coherent picture of "the first industrial revolution." This volume will be much used by students of history, although it will seldom be by the elbow when the facts have been summarized and the thinking begins; it has little of interest for the economist.

The main shortcomings of *The First Industrial Revolution* as a serious contribution to industrial revolution studies are structural and analytical. The structure of the book is neither chronological nor functional, and three general chapters fail to give pattern or synthesis to the other chapters. A logical structure would have been to have discussed and defined "an industrial revolution," to have analyzed the factors which caused the English industrial revolution, and to have considered why the revolution occurred first in England rather than elsewhere. The phenomenon to be explained was the sustained increase in the growth of total output at a rate which was revolutionary compared with what went before. This was, obviously, the result both of a remarkable increase in the productivity of human effort and also of a notable increase in productive factors. Fortunate factor endowment had much to do with England's growth, but the relative roles of increasing factor supplies (land, labor and raw materials, especially coal) and increasing productivity (the result of changing technology and organization, and of improved physical and human capital) are not adequately discussed. Nowhere does Miss Deane make clear what the industrial revolution was—in terms, for example, of the changing composition of output, or of the changing structure of the economy—or why growth occurred. And where the role in growth of particular factors is discussed, she is almost always inconclusive. Agriculture, for example, is first given a causal role—to provide food for a growing population, to inflate purchasing power for industrial products, to provide capital for industry—and then has it taken away. "The transformation in agriculture was contemporaneous with the transformations in industry, trade and transport, and is best regarded as part and parcel of the same process." It is much the same with other factors which Miss Deane considers were relevant to English growth, and whose relationships are described with phrases that are vague and analytically unhelpful: "contribute to the effectiveness of," "help to precipitate," "made a massive contribution to," etc. Thus, the process of growth remains

elusive, which is surprising, considering that there was a most interesting and original analysis of the mechanics of eighteenth century growth in *British Economic Growth, 1688-1959*. Here, instead, are a number of largely unrelated chapters on particular topics; here is a description of the English economy before industrialization but no analysis of the structural relationships; and here, although there is some identification of the relevant variables of English economic growth, there is little attempt to show how they changed and interacted to produce growth. And so Miss Deane ignores or avoids some of the leading problems raised by the historians of the industrial revolution and by the economists of growth. Was there "a take-off"? Was the revolution a revolution with a clearly defined turning point, or was it the culmination of an evolutionary process? Miss Deane weakly argues that "to understand the process of economic change one needs to take both approaches into account." Did the industrial revolution proceed from a broad or narrow base? Was it an example of balanced or unbalanced growth? Were there necessary prerequisites? Does Miss Deane's ordering of chapters—on demography, agriculture, commerce, and transport, in that order—imply allegiance to a stages theory of growth? Is English economic growth relevant, as the Preface implies, to the problems of the growth today of underdeveloped economies? These and other important questions are not answered. At least on the last question, it should be stressed that any justification for the study of the first industrial revolution based on its usefulness for growth theorists and planners of today represents a misguided rationalization to make history seem relevant when it is almost entirely irrelevant. England in 1700 had a more advanced society and economy than most underdeveloped countries of the modern world had before they began painfully to grow; and England's example, for this and other reasons, is almost certain to mislead rather than to instruct those interested in modern underdevelopment.

MAX HARTWELL

Nuffield College, Oxford, England

A Study of Contemporary Ghana. Vol. I, The Economy of Ghana. Edited by WALTER BIRMINGHAM, I. NEUSTADT, AND E. N. OMABOE. Evanston: Northwestern University Press, 1966. Pp. 472. \$12.50.

Here is a book of the type for which beleaguered teachers of economics in the universities of the underdeveloped areas cry. Prepared by three contributors (Killick, Szereszewski, and E. N. Omaboe, only one of whom is listed on the cover), it constitutes a broad survey of the economic structure, institutions, and major policy issues of a particular nation—Ghana. It not only gathers widely scattered material from a variety of less readily accessible sources but also provides new data and original effort in a number of previously neglected areas. Moreover, it assumes very little previous training in economics on the part of the reader. Apart from providing a mine of statistical information for those having little familiarity with the Ghanaian economy (it contains some 140 tables), it can serve as a first-rate text for undergraduate economics students and other general readers in Ghana. It is the first book of its type in

tropical Africa. One must hope that it may serve as a model for similar efforts in other nations.

It is difficult to convey the degree of comprehensiveness of this volume. Let me very briefly summarize what is in it. The general macroeconomic picture of recent economic performance and the sectoral and regional structure of the economy are sketched in the first quarter of the book. This part also includes a summary chapter on consumption patterns. This is followed by wide-ranging discussion of labor and capital inputs in Ghana, occupying nearly another quarter of the total. The longest part of the book is a more detailed consideration of the principal sectors—agriculture, mining, industry, finance, etc. Some relatively slight (for an avowedly socialist state) consideration of the governmental role in the economy makes up the concluding section.

Its approach is workmanlike and undramatic. It has few daring ideas and no fancy tools. Its scholarly caution about the limitations of the available statistics and the tentativeness of conclusions drawn from them are thoroughly admirable; although it must be said that they so permeate the analysis that the fledgling economist may be driven by them to despair. These factors make much of the book fairly dull reading. Particularly is this the case in the long and inconclusive analysis of labor productivity and in the fruitless attempt to measure total capital stock by adding "conventional" measures to the discounted value of returns from future cocoa production. At the same time there exists some gems of information collection and analysis; those of most general interest are probably the chapters on cocoa and the Volta Project. How many know, for instance, that the Valco smelter in Ghana will produce aluminium out of alumina, sent from America, which is itself processed from Jamaica bauxite, while Ghanaian bauxite is exported for processing to Scotland?

A good test of the usefulness of such a book is the extent to which its analysis is rendered invalid and its material irrelevant during the publisher's "gestation period." On this test, despite the recent upheavals in Ghana, this volume stands up quite well. Ghana's economic difficulties of 1965-66, undoubtedly a major factor in the government's downfall, were already visible to the writers in 1964, though they themselves were not always in full agreement on the issues.

The imposition of import controls towards the end of 1961, for instance, was seen by Killick as a "short term expedient" which despite its disadvantages was, when coupled with price controls, "one of the very few lines of reasonably effective action that is left open" (p. 428). In his view, forced reductions in the demand for imported consumer goods "will tend automatically to create additional savings" (p. 427), although he admits that if restrictions appear to be permanent this analysis will no longer apply. Against this, set Omaboe's more pessimistic and unfortunately more accurate view: "Import controls have probably come to stay and with them the previously most effective safety-valve for inflationary forces in the economy has been sealed" (p. 29).

Inflation was already recognized as a major and growing problem in 1963 and 1964. Killick argues persuasively that even if rapid inflation were to raise the savings rate, which is by no means certain, it would not raise the growth rate since the key bottlenecks were (and presumably still are) those of foreign

exchange and high-level manpower rather than that of savings (pp. 417-22). The fall in real wage rates as a result of the extraordinary wage restraint, which itself was the result of the "unity of purpose of the union leaders and the CPP" (p. 143), was already very evident in 1963. At the end of that year the real wage rate was already well below the levels of 1939, though it was to fall still further. The authors might have provided a little more explanation of how this degree of "squeezing" was achieved. Despite their illegality, strikes did, after all, take place in Ghana.

There were other signs of impending difficulties. Unemployment in 1960, a good year, was already 10 to 15 per cent of the male wage-labor force (p. 149). The tendency of food production to lag and the possibility of distribution bottlenecks was also already recognized (p. 228). So were the failures of most of the public corporations.

A full account of the economic policies of the CPP government in its final years of power still has to be written, but Omaboe, in the closing pages of this book, throws out many hints as to the difficulties as viewed from within at the time. Here he refers to "differences which sometimes develop between the Government and the planners"; he notes that "civil servants have had to struggle hard to catch up with the politicians" and that frequently "some commitment is entered into before the civil servants are called in and they are therefore handicapped in the application of their skill and experience" (pp. 460-61). The inadequacy of the machinery for economic and financial decision-making, more crudely the unwillingness of the political to listen to the technical seems to have been largely responsible for the failure of economic policy and development planning in Ghana.

Killick, Szereszewski, and Omaboe deserve great credit for their painstaking work on the Ghanaian economy. Perhaps they can be encouraged shortly to return and add the even more interesting story of the 1964-67 period to the basic structure of their account.

Economic Research Bureau, University College, Dar es Salaam

Growth without Development—An Economic Survey of Liberia. By ROBERT W. CLOWER, GEORGE DALTON, MITCHELL HARWITZ, AND A. A. WALTERS, WITH ROBERT P. ARMSTRONG, JOHNETTA COLE, ROBERT E. COLE, AND GEORGE LAMSON. Evanston: Northwestern University Press, 1966. Pp. xv, 385. \$12.50.

Foreign Investment and Development in Liberia. By RUSSELL U. McLAUGHLIN. New York: Frederick A. Praeger, 1966. Pp. xiii, 217. \$15.00.

In 1961 and 1962 a team of economists conducted a detailed and comprehensive survey of the economy of Liberia. In their report to the Liberian government, they concluded that, while the growth of output had been rapid, little basis for future growth had been or was being created; and further, that this unsatisfactory state of growth without development was largely attributable to bad government. For obvious reasons, the government of Liberia did

not release this report, but in shortened and edited form, this study by Clower and his associates has now become available. Development economists and African specialists will welcome the detail this work presents on national income accounts, foreign concession agreements and performance, institutional arrangements with respect to land and labor, educational policies, and labor surveys. The roughly two-thirds of the book which deal with these specific aspects of the process of economic change in Liberia contain hitherto inaccessible descriptive detail and perceptive analyses.

In the more general parts of this book, the authors recognize "... that a certain amount of *undirected* [italics supplied] social and political change has accompanied ..." the sharp structural changes in the economy (p. 245), but they argue that Liberia remains "... a prime example of both an 'enclave' and a 'dual' economy" (p. 4). Transformation of the subsistence sector has been prevented by the persistence of "... deleterious government practices carried over from ... pre-World War II Liberia" (p. 384). Hence, their argument continues, *deliberate* changes in government administrative, fiscal, and educational policies are needed in order to alter the social, economic, and technological dimensions of tribal life, and in order to distribute national income in a manner consistent with social justice. From the authors' pessimism regarding the likelihood of such changes follows the conclusion that the outlook for development in Liberia is at best uncertain.

The essence of the argument of Clower and associates is a preference for orderly, deliberately planned growth which generates a distribution of income and political power which is fair by Western standards; such growth is called "development." Liberian growth has relied on *laissez faire* incentives and has been substantially undirected. It has been marked by corrupt and wasteful practices, has yielded a highly skewed income distribution, and *it has been remarkably rapid*. Although there are obvious pitfalls in such a comparison, the growth experience of the post-Civil War United States could be characterized in much the same way. There is no scientific evidence that such a growth process results in less rapid achievement of a high standard of living by all of the population or causes more social conflict and disruption on the path to affluence. The Liberian experience may provide an example of a currently unfashionable, but nonetheless effective, approach to the problem of underdevelopment. Hence the thesis of *Growth without Development* is based in part on an unacceptable value judgment, and in part—as I shall point out below—on a mistaken belief that political and social institutions in Liberia are static.

McLaughlin's short and heavily footnoted book is derived from his 1958 doctoral dissertation, but it has been expanded and revised on the basis of his experience as an economic advisor to the Liberian Office of National Planning during 1963 and 1964. His extensive references usefully complement the Clower book, which, contrary to what one expects from a survey, almost totally neglects all other work on Liberia and West Africa. The first three chapters of *Foreign Investment and Development in Liberia* present in general terms the social and geographic background, and then describe the growing role of foreign enterprises in the economy. Next, there are chapters on labor; savings, investment, and exports; external assistance; and finally, a summary chapter.

The latter chapters are the more interesting, since a more concise and equally current general description of the structure of the economy has been available for some time.¹

In contrast to the thesis of *Growth without Development*, McLaughlin argues that "social and institutional factors which (are) . . . causes of underdevelopment are undergoing change in Liberia" (p. 196), and that heavy foreign private investment and public assistance has provided a basis from which a self-sustained process of economic development can emerge. In his view, development of the nation's human resource potential, and domestic entrepreneurs who will engage in domestic capital formation, are the crucial needs. The chief merit of McLaughlin's book is its emphasis on the continuing modification of social and political institutions which has resulted in significant changes in the lives of ordinary Liberians in the last decade. Correspondingly, it is the inability of Clower and his associates to recognize the rapid social changes occurring in a backward social structure which constitutes a major flaw in their work. I do not see how one can ignore the social effects over the last decade of a doubling of money sector employment and a doubling of money sector real wage rates for unskilled labor, together with a growth of urban population at a rate of roughly 10 per cent *per annum*. If anything approaching these rates of change is maintained, the subsistence sector will have disappeared in a generation or two.

Another serious fault of *Growth without Development* is that it is badly out of date. Since all the material in the book dates from 1962 or earlier and no attempt has been made to update it, the incautious reader may frequently be misled. For example, half of the total resource transfer to Liberia through foreign assistance has taken place since 1962. This makes Chapter 12 on Foreign Aid and its appendix obsolete.² Again, LINEC (p. 141) has been dead since 1963, and the Mt. Coffee hydroelectric project, which was to have been financed by LINEC, has been largely financed by AID. By far the largest public investment project in the country, it will come on line in 1967. Chapter 5 on Planning and Fiscal Policy and its appendices are likewise obsolete: government revenues have been functionally classified for several years; the collection and dissemination of statistics have vastly improved; and, contrary to the view that "It will always pay Liberia to import steel . . ." (p. 101), Liberia has a comparative advantage in steel production, and negotiations are in progress to establish a West African steel mill at Lower Buchanan. Revision of the debt service schedule was completed in early 1964, and annual payments are about two-thirds of the \$15 million figure given (p. 26).

Two relatively technical points should be made with respect to the national accounts data for 1960 presented in both books. First, the imports figure in the national accounts exceeds the f.o.b. figure for imports in the Liberian trade

¹M. A. Qureshi, Y. Mizoe, and F. d'A. Collings, "The Liberian Economy," *I.M.F. Staff Papers*, July 1964, 11, 285-326. Strangely, neither book under review refers to this article.

²Incidentally, the popular practice, employed in both the books under review, of measuring foreign assistance by *obligations* rather than *disbursements* or *expenditures*, is one to which I take strong exception.

statistics by some \$14 million, but is specified to be f.a.s., which should make it smaller than the f.o.b. figure. Moreover, the logic of the national accounts requires that c.i.f. figures be used. Secondly, the difference between gross national product and gross domestic product is net factor income paid to nonresidents. Since the earnings of expatriates were roughly \$30 million, and many, if not a majority of them, were effectively nonresidents, the difference between GDP and GNP would appear to be roughly \$55 million rather than \$35 million. This correction reduces per capita national income to \$100 from \$125, which is surely a significant change.

In summary, McLaughlin's book lacks an index and needs editing. Its high price makes it unsuitable as an introduction to the Liberian economy. For the African specialist it is lacking in detail and for the development economist it offers few new insights. *Growth without Development* has serious faults, but it is well written and may be read with profit.

PAUL B. HUBER

Dalhousie University

Economic Development and Export Growth: A Study of Northern Rhodesia, 1920-1960. By ROBERT E. BALDWIN. Berkeley: University of California Press, 1966. Pp. xviii, 254. \$6.00.

This study is a welcome addition to the literature of case studies of economic development. While the author's primary concern is with the factors determining the pattern of economic expansion in a single country, his argument is developed within a wider framework. Baldwin's central thesis—presented earlier in his *Economic Journal* article of 1963, but here developed more fully and supported with detailed empirical findings—is that the technical characteristics of the production function in the pioneer export industry are crucial determinants of the pattern and pace of economic change in an underdeveloped economy. This approach permits a broad differentiation between two types of underdeveloped economy: (1) those in which the export base is organized around large-scale enterprises created by external capital and enterprise; and (2) those in which the export base is built up around the outputs of peasant producers. Though his book is intended to deal systematically only with an economy of the first type, its organizing theme is a useful counter to the unfortunate (though still prevalent) propensity of some commentators to generalize about underdeveloped economies as if they comprised a homogeneous group.

As Baldwin successfully demonstrates, the export technology hypothesis has considerable explanatory power in the case of Northern Rhodesia (Zambia since 1964). Dating from the 1920s, the base of monetized economic activity has been built up around copper mining, an activity which, in the circumstances, was highly capital intensive. In the formative stages, three inputs were required for the successful conduct of operations: capital, skilled labor (supplied from abroad), and unskilled labor (supplied locally). Such productive combinations permitted a rapid growth of monetized geographical prod-

uct, but in other respects these arrangements blunted the spread of developmental stimuli. The resulting distribution of income was not conspicuously favorable to the local build-up of secondary lines of production. A substantial share of after-tax profit was typically repatriated and the wage bill of Europeans (which exceeded that of Africans by a considerable margin) was characterized by high propensities to import. In addition, the extent to which a highly capitalized export industry could generate backward linkages was severely limited. In only a few cases was local production of the intermediate products required by the dominant export industry economically feasible.

Though the technology of the dominant export industry can take one a long way toward an understanding of the Northern Rhodesian case, it is not alone sufficient to account completely for the resulting economic structure. Baldwin quite properly notes that social and institutional forces which have supported a "dualistic" economic pattern have also been significant in shaping the outcome. Though "dualism" has been manifested historically in the allocation of governmental expenditure and in agricultural marketing arrangements, its impact has been most visible in the wage labor market. Originally, a gulf between the wage scales of Europeans and Africans reflected a divergence between the demands of the mining industry for skills and the capacity of the local population to satisfy them. Later, this pattern was propped by artificial supports and, for a considerable time, the advancement of African wage earners was frustrated. Events of the past decade have erased much of the discriminatory basis of wage employment. Yet, as Baldwin correctly points out, the allocative distortions associated with an anachronistic wage structure survive. He writes: "A small group of Europeans and urban Africans, who possess monopolistic labor power, have gained, at the expense of Africans in the rural areas and in the low-paying service industries in urban areas. The latter group does not have the economic or political power to prevent the massive misallocation of labor resources which is being frozen into the economy" (p. 108).

Baldwin's account of the impact of export technology on the growth process, it should be noted, does not rest on an assumption of fixed coefficients in export production. On the contrary, he insists that, over a substantial range of activities, there is considerable scope for variation in factor combinations. The bulk of one chapter is devoted to an analysis of the adjustment of the copper mining groups to changing terms of factor supply—in particular, to upward pressure on African wage rates during and after World War II—and it makes excellent reading. This process has generated a redefinition of jobs within the industry and the opening of higher-rungs on the skill ladder to African miners, but it has also been associated with a substitution of capital for labor.

The export-technology thesis—even when qualifications have been added—is nevertheless strong enough to override an alternate hypothesis on arrested development in Northern Rhodesia. The line of interpretation which links retarded economic advance with the failure of Africans to respond positively to the emergence of new economic opportunities is explicitly rejected by Baldwin with the aid of fresh data from the records of the copperbelt mining companies. His attempt to demonstrate a positive supply response by African farm-

ers to price incentives is less satisfying. Lacking data for Northern Rhodesia, Baldwin puts multiple regression analysis to work on material gathered by the Southern Rhodesian Department of Native Agriculture. The reliability of these data is even more dubious than the author's numerous caveats allow for.

In Baldwin's view, the "educative" impact of unfamiliar techniques on labor efficiency offers partial compensation for the failure of a high-technology export base to generate more dynamic demand stimuli for growth. Within the confines of the dominant export industry, the point is well taken. It must be emphasized, however, that the numbers directly affected are small, both absolutely and relative to the size of the population of working age; in 1962, for example, the copper industry engaged fewer than 35,000 African employees. Meanwhile, the bulk of the population in traditional agriculture has largely been bypassed during the postwar period of remarkable expansion of export receipts and of money national income.

As a well-documented and well-argued discussion of a special type of economic expansion, this book can be read with profit by students of the underdeveloped world.

Wesleyan University

Statistical Methods; Econometrics; Social Accounting

The Identification Problem in Econometrics. By FRANKLIN M. FISHER. New York: McGraw-Hill Book Company, 1966. Pp. xi, 203. \$8.95.

This addition to the Economics Handbook Series consists of six closely written chapters on the identification problem, a topic which receives only limited attention in textbooks on econometrics. The material which is covered in the book is based primarily on Professor Fisher's recent work on identification and includes several extensions of his previously published results. As such, the book provides an excellent survey of the current state of the identification problem.

The first two chapters are devoted to a discussion of the problem of identification and the usual textbook results. The identification problem is introduced within the context of a single-market model. The discussion of this model in both the stochastic and nonstochastic cases sets the stage for the following investigation. In Chapter 2 the rank and order conditions are derived for identifiability of an equation under linear restrictions on the coefficients which enter the equation. An interesting discussion of identifiability and the use of two-stage least squares and k -class estimators is also included in this chapter. In particular, the way in which these estimation procedures break down when applied to an equation that is not identified is described.

The remainder of the book includes material which is referred to only casually, if at all, in most econometrics textbooks. Chapter 3 is devoted to a discussion of the use of restrictions on the size of the variances of the disturbance terms in the model to (nearly) identify one equation with respect to another

equation or set of equations in the simultaneous equation model. The effect on identifiability of zero restrictions on the off-diagonal elements in the variance-covariance matrix of the disturbance terms is described in Chapter 4. This leads naturally to the theory of recursive and block-recursive systems. Again necessary and sufficient conditions for identifiability under coefficient and covariance restrictions are derived for general systems and applied to the special recursive and block-recursive cases.

Identifiability criteria for nonlinear systems are developed in Chapter 5. Two types of nonlinearities are separately considered: systems which are linear in the disturbances and parameters but nonlinear in the variables, and systems which are linear in the parameters, variables, and disturbances, but in which the parameters are subject to nonlinear constraints. These two types of nonlinearities are shown to arise in the nonlinear case when the equations of the system are expanded in a Taylor's series. Necessary and sufficient conditions for identifiability in each case are then derived. The final chapter is devoted to a brief discussion of "other topics" including autocorrelated residuals and tests of identifying restrictions.

In the author's words "the book is intended for students of econometrics and is meant to be read in conjunction with the study of simultaneous equation estimation." The reader is therefore assumed to know the rudiments of matrix algebra and to possess a modicum of statistical knowledge. Although estimation is mentioned briefly in several parts of the book, the material is confined almost exclusively to the essentially mathematical problem of identification.

The exposition is enhanced by a fairly liberal use of simple examples to illustrate the basic problems and theorems. Comprehension of the results is facilitated also by supplementing the mathematical proofs with geometric and intuitive explanations. Despite this it is the reviewer's feeling that many readers will not find this an easy book to master. The interests of most readers might best be served by studying carefully the first two chapters and then working through the remaining material as specific research problems arise. The practicing econometrician will find that this book provides a comprehensive statement of the currently known results on identification in simultaneous equation models.

Income Distribution in the United States. By HERMAN P. MILLER. A 1960 Census Monograph. Washington, D.C.: Supt. Docs., 1966. Pp. viii, 306. \$2.25.

This is the first monograph from the *1960 Census*, and the profession is indebted, as it was for the 1950 Census Monographs, to the Social Science Research Council's sponsorship, and to funds from the Russell Sage Foundation. This time the Equitable Life Assurance Society also provided some financial support. Herman Miller, who wrote the income monograph on the 1950 Census is again the author, and a highly appropriate choice, since in the meantime he

has produced a number of excellent special studies of income and a popular book on the subject.¹

The yeomanlike but necessarily dull task of presenting basic background information and data is enlivened by clear summaries of the more interesting findings. Decimal census data are supplemented by annual data from current population surveys. The reader first discovers that from 1947 to 1960 there has been very little change in the inequality of the distribution of money income among "families and unrelated individuals," to use the cumbersome Census method of indicating that they have not removed one-person families for separate treatment. The apparent stability remains whether one uses the share of income going to the top 5 per cent or 20 per cent or the Gini coefficient, even when one looks at subgroups of the population by age, location, employment status, whether the wife worked, or family size. The focus on inequality does divert attention from the income revolution during the period to which Katona has drawn attention, vastly increasing the amount of discretionary income and the proportion of people whose incomes are above some minimal level of adequacy.

There follows a description of trends in the demographic characteristics of the different income groups, classified by current dollars, then constant dollars, and finally by income quintiles. The changes are small and in the expected directions. A more interesting tabulation shows, for 1959 only, the sources of income of those in different income groups.

Then come three chapters of detail on incomes of those in different occupations and industries, serving to dramatize the fact that between 1939 and 1949 the greatest relative gains in income were made by the lower paid workers, while during the period from 1949 to 1959 the greatest relative gains were made by the higher paid workers. The author refrains from any extensive speculation about the relative roles of war, peacetime affluence, or the party in power in producing these trends. The detailed occupational data provide some striking evidence of the difficulties certain groups experience during periods of rising prices and incomes of their own salaries are difficult to change. It was not only the civil servants who were worse off, but also the clergymen, who fell five decile positions in spite of increased church activity and membership during the period. The trends in dispersion, and in incomes by industry group are less interesting.

The reader who has plowed through all these carefully worked-over and meticulously presented data, wondering why education was never mentioned, is finally rewarded by the best chapter in the book—one on income and education. Its main contribution is not the data from the 1960 Census, but the use of trend data to select the same cohorts (generations) at different points in time (years) and prove that age differences from a single cross-section under-

¹H. P. Miller: *Income of the American People* (New York, 1955), "Annual and Lifetime Income in Relation to Education," *Am. Econ. Rev.*, Dec., 1960, 50, 962-86; *Rich Man, Poor Man: The Distribution of Income in America* (New York: 1964), *Trends in the Income of Families and Persons in the United States 1947 to 1960*, Tech. Paper No. 8, U.S. Bureau of the Census (Washington, D.C. 1963). The last item contains a number of detailed tables not included in the monograph.

state the income increases people can expect because they leave out the influence of general upward trends in earnings. Indeed, it is possible to separate the increases experienced by a particular cohort with a particular level of education into those resulting from the passage of time, and those from the accumulation of experience and seniority.

Finally, there is an extensive methodological appendix providing data on various evaluation studies comparing Census income data with data from other sources, from the Current Population Surveys, and from reinterviews conducted by the Census bureau.

There is little to criticize about what was done. The editing and checking was obviously well done. The qualifications required in using and interpreting dollar money income, measured before most taxes and after most transfers, are carefully stated, although the reader is left with the impression that their relative importance is unknown. Other data do exist that allow one to "quantify the qualifications" at least roughly.²

At one point, a surprising impression is left that, poverty being relative, we shall always have it with us. This is a counsel of despair, since it is clearly possible to define poverty meaningfully as having an income less than some fraction of the average income of those with the same sized family, say a third. Such a definition is unaffected by inflation or change, yet poverty so defined could be eliminated. There will always be people below the average, but there need not be anyone below a third of the average!

In a few places the reader is left dangling. A multiple regression using education and some other things to explain 1958 income data from the Current Population Survey is mentioned, and the coefficient of multiple correlation given, but none of the regression coefficients nor any measure of the importance of education nor any reference. A few sentences later, reference is made to a National Science Foundation study showing that "only" 75 to 80 per cent of the 17-year old boys who rank in the upper 30 per cent of their high school class go to college, but no data are given by income groups or on the proportions with lower rankings who go to college. The original data show that there is an income effect within ability rankings, but they also show that very few of the low-ranked high school students go to college. The implication is that, if there is wastage of talent, it reflects the opportunity cost of not investing in the education of some talented youth, rather than a wastage of educational resources educating those without talent.³

Every reviewer yields to the temptation of describing a book he would have preferred to see written, unfair as it may seem. There is a crying need for

² See J. Morgan, M. David, W. Cohen and H. Brazer, *Income and Welfare in the United States*, New York 1962.

³ For basic data see the testimony of Willard Wirtz, *Hearings on the Employment Opportunity Act of 1964*, Subcommittee on the War on Poverty Program, House Committee on Education and Labor, 88 Cong., 2nd sess., March 19, 1965. See also C. B. Nam and J. D. Cowhig, "Factors Related to College Attendance of Farm and Non-farm High School Graduates 1960," in *Farm Population Ser. Census-ERS (P-27)*, June 15, 1962, which also shows a relatively high correlation between high school grades and IQ on the one hand and college attendance on the other.

some things that are not in this book, and since there will certainly be a 1970 Census Income monograph, we should urge them for next time. First, we'd suggest less attention to occupation. The definition of an occupation is difficult, its meaning unstable, its dimensions multiple, and its attachment to an individual loose. More attention to education, and where that education was received, is in order. This is particularly so in view of current arguments about the quality of education. Second, more attention to the things that are causing changes in income would help: undoubling of families, changing numbers and types of extra earners, more couples still working, but whose children have left home, and reduced unemployment and increased availability of overtime and second jobs.

Third, more attention to the welfare implications should lead to more detailed tables by family size and by number of earners. And more attention to the distinction between the private and social return to investment in education calls for analysis of *hourly* earnings, if one wants a measure of the potential social payoff unalloyed by the impact of unemployment, extra work and second jobs, or the tendency for high-salaried people to take their vacations. We should not attribute the low incomes from unemployment in 1959 to lack of education rather than social policy, nor the possibly increased incomes of the uneducated by 1969 if they have all the work they want then, to a reduction in the social return to investment in education.⁴

Finally, if we are to pay continued attention to the distribution of income, it is time someone attempted to assess its meaning and changes in its meaning, under the impact of the changing importance of nonmoney rights to retirement programs, unrealized capital gains, changing impact of the tax and transfer system, etc., paying attention to and attempting to quantify some of the issues so persuasively raised by Richard Titmuss.⁵

In the process, it may well be necessary to make use of data other than those produced by the Census Bureau in order to allow a richer interpretation of the Census data.

Linear Programming. By MICHEL SIMONNARD. Englewood Cliffs, N.J.: Prentice-Hall, 1966. Pp. xiii, 430. \$12.00; text, \$9.00.

Linear Programming is a topic already covered by an impressive array of texts-and-references. The translation (and extension) of the Simonnard book by W. S. Jewell provides a valuable addition to the existing collection of good books (in English) on linear programming.

The Simonnard book is favorably distinguished by its treatment of the mathematical and computational aspects of linear programming. The strategic problems of topical coverage and sequence, the tactical problems of proof and argumentation, and the articulation of the whole by a precise and economical

system of notation are all solved admirably in this book. The reader seeking a lucid, comprehensive exposition of the logical and computational mechanism of linear programming should be well pleased with the Simonnard book. In my judgment, the first ten chapters of this text—which cover general linear and integer programming—are not surpassed, as mathematical exposition, by any existing text.

All this is achieved at the expense of content likely to be dear to most economists. Economic interpretation is severely restricted in scope. While a few essential points such as the interpretation of dual variables as shadow prices are developed in a competent but cursory way, there is no pretense of a more than anecdotal approach to economic interpretation. There is, for example, no discussion of the economic ramifications of the decomposition principle. Discussion of applications of linear programming to specific managerial and technical problems is similarly restricted. These exclusions are of course part of the design of the book, and a section in the first chapter does briefly summarize major areas of application and provides some references.

Two characteristics of the book would seem fundamental to determining its appropriate use as a text: (i) it contains no exercises, and (ii) it makes comparatively severe demands on the reader's background in linear algebra and on his mathematical maturity. For students with sufficient mathematical preparation and/or capability this should provide an excellent text and reference.

The content of the book is divided into four main parts: (i) general theory and methods of calculation for linear programming; (ii) integer programming; (iii) theory and methods for special structures—mostly transportation networks; and (iv) three appendices that provide needed results in linear algebra, the theory of convex polyhedra, and graph theory.

Although the mathematical and computational orientation of the Simonnard book makes it an unlikely first choice reference for most economists, the economist with a special interest in linear programming is very likely to find in this book new insights and best expositions of several fundamental topics in linear programming. Beyond this, the Simonnard volume emerges in W. S. Jewell's translation as a deft and careful piece of intellectual craftsmanship.

Economic Systems; Planning and Reform; Cooperation

A Reappraisal of Marxian Economics. By MURRAY WOLFSON. New York and London: Columbia University Press, 1966. Pp. xvi, 220. \$6.75.

In this book the author attempts many things: a critical survey, from a broadly positivistic position, of the philosophical background of Marxian economics, including a sketch of the background in European philosophical history as well as Marx's own philosophical position; a discussion of what he conceives to be the crucial technical aspects of Marxian economics from value theory through cyclical crises; and a discussion of post-Marxian theories of, among other items, revisionism, imperialism, economic growth in developed

and underdeveloped economies, collective bargaining, and the effects of U.S. foreign investments. All this in a rather slender volume of 190 rather loosely printed pages of text.

A century of criticism and counter-criticism has shown that what Marx "really meant" is obscure. No account of Marxism can be written that cannot be subject to the criticism that (in the eyes of the critic) important passages and possible interpretations have been neglected. In a sense anyone can be his own expert on Marxism. (And nothing is more deceptive than to assert, seemingly straightforwardly, that one is assuming that Marx meant what he said. What did he "really" say?) Thus in reading this review one should bear in mind that questions of omission and interpretation are to a degree matters of taste.

Wolfson's position differs from many recent writings by anti-Marxists, sympathetic non-Marxists, and Marxists, in that he feels that fruitful studies of Marx cannot take him piecemeal. The basic philosophical background is intimately tied to his philosophy of history, which produces his theory of value, which determines his theory of exploitation, which leads inevitably to immiserization, crises, and the breakup of capitalism. The author assigns himself the task of examining this structure for its bearing on what he takes to be the crucial socio-economic issues of our time.

The initial philosophical discussion (Ch. 2) will require careful reading, because of its brevity, unless one is already fairly well versed in the history of European philosophy. This is a (minor) disadvantage since I believe that Wolfson touches upon an important truth in his emphasis—contrary to most writers—on the philosophical background of Marx's treatment of value. While doubtless derivative from Ricardo, the entire question of value vs. price and the transformation problem is difficult to imagine unless Marx started from a belief that the purpose of science is not the investigation of "superficial" empirical or phenomenal forms, but the essential noumena which "lie behind" appearances.

From there Wolfson devotes three extensive chapters, which form the main body of his work, to an analysis of Marxian economics in the narrower sense. The first (Ch. 2) deals with value defined as the labor content of a commodity. Contrary to most authors he chooses to ignore entirely the vexed questions of value and price, relative capital-labor ratios, and the transformation problem. Nevertheless, his critique of Marx generally follows neoclassical lines. He points out that ratios of exchange do not follow the "substance" of value (labor time) because of diminishing returns to land, the effects of tastes on the demand for commodities and the supplies of different types of labor, and differences in ability affecting supply.

In another major chapter (3) Wolfson turns to the value of labor power or the wage. If I interpret him correctly he argues that the crucial question is whether, given savings propensities and rates of population growth, technological change is sufficiently biased in a labor-saving manner to produce increasing misery. He concludes that Marx does not demonstrate that this will necessarily happen.

At this point the discussion becomes somewhat murky to this reviewer

caused by some combination of Wolfson's misunderstanding of Marx, obscure exposition, or weaknesses in theory, and/or, perhaps more likely, my own lack of understanding. He appears to argue not only that technological change will not necessarily produce increasing misery, but that the labor theory of value requires the wiping out of surplus value in equilibrium; "since *ex hypothesi* the capitalists perform no service requiring sacrifice under perfect competition they would receive no profit" (p. 110). He contrasts the labor theory of value with a supply and demand theory and "entrepreneurial productivity." But Marx did in fact have a supply and demand theory; the dispute about "productivity" is merely terminological. To measure quantities in labor units, as Wolfson has previously interpreted the labor theory of value, may be cumbersome but it cannot change anything substantive. Indeed he quotes Marx on how the capitalist responds to rising wages by reducing accumulation (with a lag) and keeping capital scarce (and therefore "productive" to the neoclassical economist). The lag produces the "real" cycle of Volume I which is analytically distinct from the aggregate demand cycle of Volume III—a distinction which the author does not appear to make.

Since Wolfson concludes that labor threatens to swallow up, in Marx's scheme, the total social product in competitive equilibrium, he turns to the cycle and crisis discussion in Volume III for the clue to increasing misery and capitalist breakdown. Increasing misery requires increasingly severe crises, and again he concludes that Marx has not established such a tendency. The conclusion is partly based on the logical confusion in having simultaneously declining rates of profit, constant wages, and technological progress; it is partly based on the fact that it cannot be put to a refutable test.

To this reviewer, Wolfson, like many commentators, underestimates the extent to which the breakdown can be derived with the apparatus of Volume I. There is no *logical* reason why technological change could not produce increasing misery, and with it a degree of political instability that would end in revolution as described in this volume. Of course there is no empirical evidence that there is even a technological tendency in this direction. But this does not prevent the idea from reappearing regularly, from Sismondi to Robert Theobald, whenever unemployment comes up for public discussion.

There follows a discussion of Leninism and revisionism applied to virtually the whole gamut of modern domestic and international economic questions. A critique of these points cannot be undertaken here, but in the reviewer's opinion the treatment is marred by gaps in the theoretical reasoning. In general Wolfson supports the revisionist view that collective bargaining and full employment policies remove the necessity or desirability of revolution. Wolfson's own opinions on the determinants of the distribution of income can be indicated by his argument that it is plausible that

... wages are negotiated on the basis of bilateral monopoly in which a single seller of a commodity confronts a single buyer of it . . . there is air of greater reality about a class bargaining wage contract than one which starts from the labor supply composed of individuals' willingness to work or rest and a demand by atomistic capitalists based on the increase in output they can obtain by hiring an additional employee (p. 114).

Consequently he is inclined to believe that the higher standard of living produced by capitalism is "in large part . . . due to the pressures of the organized labor movement itself" (p. 189).

If one were forced to choose between this model of wage determination, in this century and last, and "perfect competition" with which Wolfson contrasts it, this reviewer would opt for the latter. But of course one is not required to. There is a curious double standard that the author applies to Marx's theory and his own. Dealing with Marx he applies the supply and demand analysis of neoclassical economics. Considering that in the U.S. economy approximately one-quarter of the labor force is unionized and that obviously collective bargaining is broken up into thousands of separate bargains, why does this apparatus not apply?

DONALD F. GORDON

University of Rochester

Goals, Priorities, and Dollars. By LEONARD A. LECHT. New York: The Free Press; London: Collier-Macmillan, 1966. Pp. xiv, 365. \$6.95; paper, \$2.95.

The main point of this "first study" is to provide information that will be helpful in charting the course of economic policy over the next decade. In it, the word goals is used synonymously with economic needs and aspirations. As indicated by chapter headings, they consist of the major components of gross national product; a number of great society programs such as urban development, social welfare, health, and education; and some miscellaneous objects of expenditure such as space travel, agricultural subsidies, and foreign aid. Confining goals thus to the objects of expenditure bypasses the confusions and policy conflicts that might derive from including such alternatives as price stabilization or economic freedom.

The result is a series of chapters which set forth facts and reasoning intended to justify estimates of the expenditures needed to achieve sixteen "goals" in 1970 and 1975. In each, tables are provided to compare actual data for 1962 with the projections to 1970 and to 1975 in constant 1962 dollars. These chapters in part embody the findings of a series of "research memoranda" prepared by members of the National Planning Association staff, all being rewritten by the author to fit a common pattern.

Throughout, the discussion conforms to the concept of progress implicit in GNP numbers, and underlying almost all of the estimates is the projection of trends, with heavy emphasis in the determination of those trends on the experience of the last decade. This in effect sets the study up as another in the NPA series of long-range projections, and it accordingly leans heavily on previous works, as indicated by numerous footnotes and by such expressions as "a high consumption economy." No reconciliation is made to adjust these figures to the estimate of feasible production, which, on the basis of a growth rate of 4 per cent is estimated at almost \$1,000 billion in 1975. For this reason, the specific numbers provided may be somewhat less useful than those in the previous volumes.

The general procedure is first to project a base below which future expendi-

tures should not fall by adjusting 1962 totals upward for changes in population, and then to calculate the goals in terms of the improvements over 1962 standards which we may expect to achieve in the next decade. It is apparently assumed that we shall be pursuing enough of these goals so that effective demand will at least match our production capabilities. Except for this assumption, the problem of how we are to get there is ignored.

The basic conclusion is twofold: we are not bound by any stricture of scarce resources from achieving further great progress in meeting our wants; but we cannot have everything because the total needs exceed our production capabilities. If anything, the report seems to lend stronger support to the former position; for the total of our "aspirations goals," with much irrelevancy and waste in the estimates, exceeds feasible production by only 15 per cent.

This last impression is enhanced by the fact that this medley of "guesstimates" and proposals projects major percentage increases in everything except national defense and agriculture. The costs of remedying social disutilities, such as urban sprawl, with its excessive transportation requirements, or air and water pollution combine with better diets and living quarters for the poor as parts of a single grand total. There is a naïve acceptance of the world as it is and may be expected to develop. Everything goes, provided only that it conforms to established norms of acceptability. To illustrate: "Expectations of steadily rising living standards . . . are cultivated by mass advertising, by the easy availability of consumer credit, and by the emphasis on "getting ahead" or at least "keeping up with the Joneses" (p. 53). Putting up everything that adds to the dollar total, without qualitative judgments about what contributes to welfare, seems to embody an embarrassing lack of discrimination.

There is hardly any attempt to resolve potential conflicts. "Consumer information services" are proposed, and their cost is added to the consumption total, without regard to the fact that their main usefulness should be the reduction of other items that go into current consumer spending. The chapter on housing states, "experience since World War II points to the large merchant builder as the strategic element in furthering innovation in residential construction" (p. 208); but then ends with the pious hope that spending for housing "is more likely to develop a meaningful pattern for urban living if it is pursued as part of an overall development plan for our metropolitan areas" (p. 214).

In short, the book is in no sense a plan for the realization of our goals. There is hardly any effort to discover or devise solutions, and the problems themselves are described mainly as a justification for extending the expenditure estimates into new high territory. The failure to be positive is aggravated in two ways: first, by excessive use of rather vague statements that something "could be done" or "would open up opportunities for," even though specific recommendations may be intended; and, second, the use of the collective "we," or "our," in contexts where it is difficult to distinguish the NPA staff from such others as the "consensus of national leaders," the "experts" in a given field, or "knowledgeable people" in general.

These defects might have been avoided at least in part if the book lived up to the promise in the "Priorities" part of its title. Despite the fact that it

embodies the work of the Center for Priorities Analysis, it says nothing about priorities beyond specifying that priority decisions will have to be made.

Nevertheless, the volume as a whole evidences the growing need for planning under conditions of sustained prosperity in an increasingly complex economy, and the chapters on goals point to diverse activities in various fields that are at least partial attempts to foresee and resolve social and political as well as economic problems. The experts everywhere who are undertaking this role mostly speak in protest against what is wrong and, less often, but still commonly, give analytical attention to how conflicts may be resolved. The present study would have been much better if it had dared to be forthright in following their example.

Money, Credit, and Banking; Monetary Policy; Consumer Finance; Mortgage Credit

The Flow of Capital Funds in the Postwar Economy. By RAYMOND W. GOLDSMITH. New York: National Bureau of Economic Research, distributed by Columbia University Press, 1965. Pp. xxi, 317. \$7.50.

This book, the latest in the long and distinguished series of monumental statistical studies by Raymond Goldsmith, principally summarizes much of the work of the National Bureau's Postwar Capital Market Study. It draws on the immense bodies of data assembled by the large number of researchers and assistants who worked under Goldsmith's direction in the attempt, largely successful, to bring up to date and to extend Goldsmith's pathbreaking data estimates in *A Study of Saving in the United States* (Princeton, 1956) of stocks of wealth and flows of saving and investment classified by principal balance sheet item and by major transactor group. The more recent data-gathering efforts were also, and perhaps primarily, devoted to estimating experimentally a complete flow-of-funds matrix for the United States on both annual and quarterly bases as well as a detailed national balance sheet in order to provide "considerably more detailed, more accurate, systematically arranged, and integrated data on gross capital market flows, asset holdings, and interest rates. This is the field to which the National Bureau's Postwar Capital Market Study has tried to make a contribution to which this report is limited" (p. 74). The book mainly focuses on the data of capital market flows and asset holdings. It contains no detailed or systematic presentation of interest rate data but does make several attempts to use the flow and the balance sheet data. In the main these attempts are unsuccessful.

The data, presented in 110 tables and 27 charts and discussed throughout the book's ten chapters, are but a sampler of, and introduction to, the vast body of data now available in other publications of the Postwar Capital Market Study, notably *Basic Data on Balance Sheets and Fund Flows* (Princeton, 1963), the R. W. Goldsmith, R. E. Lipsey and M. Mendelson, *Studies in the*

National Balance Sheet of the United States, Vols. 1 and 2 (Princeton, 1963), and the David Meiselman and Eli Shapiro *Measurement of Corporate Sources and Uses of Funds* (Princeton, 1964), as well as the data now assembled and reported on a current basis in the Federal Reserve Board's flow-of-funds system of social accounts (see also *Flow of Funds in the United States 1929-53*, Washington 1955). The book, however, sets out to be more than an encyclopedic set of tables, for it also attempts to place the 1945-1958 postwar experience in historic perspective as well as to analyze many of the features of capital markets in the United States. The book compares some of its findings with earlier U.S. experience previously reported by Kuznets in *Capital in the American Economy: Its Formation and Financing* (Princeton, 1961) and Goldsmith in *A Study of Saving and Financial Intermediaries in the American Economy since 1900* (Princeton, 1958). This sense of historical relevance, one of the outstanding features of other Goldsmith efforts too, should be especially valuable to the new generation of economists and financial analysts—and to their teachers—whose knowledge of the pre-1929 financial and economic world generally rests on stray bits of impressionistic and inaccurate hearsay.

Unfortunately, the contribution of all these data, and the accounting statements in which they are filed, to improved understanding of financial processes and to the analysis of the capital markets is disappointing, especially in view of the substantial investment in estimating flow-of-funds accounts and the long awaited application of these data to the analysis of financial and monetary behavior. These and related data have been here for more than a decade—at least since publication of the Federal Reserve's accounts in 1955. In the attempt to make the accounts more useful and useable additional detail has been added, the accounts have been put on a quarterly basis and adjusted for seasonal variation, and the findings published on a regular basis in the *Federal Reserve Bulletin*. Yet despite this vast and continuing outpouring of data from the Federal Reserve's flow-of-funds statistical salt mill, to the reviewer's best knowledge not a single important substantive contribution in the fields of money, finance, and investment behavior has resulted from the availability of the data or from the special accounting format used to assemble and to classify the figures. Indeed, the burst of creative and fruitful work in the past decade in these fields has generally bypassed the huge data-making effort, even though these data were meant to be used in the same quest.

Perhaps the nature of the data-gathering exercise explains the tonnage of the harvest but the meager value of the crop thus far. It has largely been measurement for its own sake, so that not even Koopmans' caricature of many National Bureau efforts as measurement without theory is an accurate description of the prodigious flow-of-funds data-gathering, for here we have had measurement without problem.

The sources and uses of funds accounting format and some of the purposes to which the accounting statements are put may puzzle some readers and mislead others. One reason is that it is quite incorrect to represent, as Goldsmith does in Chapter 4 and elsewhere, the ratio of each listed source to total sources as if the numerical proportions were also indicative of the relative importance of individual items in explaining decision-making or market phenom-

ena, for example, in asserting a share of total sources accounted for by retained earnings, bank loans, or the like.

It is difficult to interpret the numerical proportions themselves because the totals and most of the separate items in the sources and uses accounting identities are neither clearly nor uniquely specified. Instead they are often highly responsive to the availability of data and to accounting practices, which are also often arbitrary. For example, the item "Total Sources of Funds" really means something like the "Sum of the Items Listed Above." The sum itself, even in principle, is not a uniquely measurable quantity such as the tonnage of coal mined in the United States during the first quarter of 1967, or the value added by Peruvian corporations in 1911. Moreover, this sum does not even represent the empirical counterpart of an economic concept in the sense that Net National Product or other of the components of the National Income Accounts are alternative measures of aggregate income, except perhaps that "Total Sources of Funds" may be the empirical counterpart of something like the supply of loanable funds, a concept which also has many of the same problems of concept and of measurement. For an example of problems posed by individual items in the accounts, depreciation may be listed as a source of funds when gross capital expenditures is listed as a use of funds or, depreciation may be netted against gross capital formation on the uses side, giving net capital formation. The latter accounting practice alters the numbers in the accounts describing capital formation as well as the item, "Total Sources of Funds." For these purposes there is no special reason to choose one treatment rather than the other, which is why the sum itself has neither analytical nor substantive content. Further, because there are no standard accounting conventions generally followed in this area by social accountants—or private ones, either—nor need that the same accounting conventions be followed by the same social accountant in treating different sectors, aggregating the figures for different transactor groups compounds the difficulties. The number finally arrives at for "Total Sources of Funds" for the economy as a whole can be made to take on virtually any numerical value depending on the aggregation, the consolidation, and the netting procedures that are adopted, just as the analogous figure for "private debt" can be made almost any number depending on how consolidated the debt statement is, even up to the point of having net private debt equal zero when the private sector (in a closed economy) is placed on a completely consolidated basis.

No doubt the scanty substantive and analytical contributions thus far from the flow-of-funds data and format have come as a great disappointment to large numbers of economists and financial analysts, many of whom have long held out hopes that these accounts would be the analog for finance that the National Income Accounts have been for aggregate income in many simple Keynesian models. In these models the level of income is essentially a function of the relationship among its components. Aggregate income as well as the data necessary to analyze changes in aggregate income are found in the accounts, and by means of Keynesian theory the accounts become a self-contained, self-explanatory body of data. Indeed, much of the current structure of the National Income Accounts is rooted in these Keynesian analytical con-

cerns. Reciprocally, much of the development of the Keynesian analysis and its widespread appeal stemmed from the availability of these data. Whatever the merits of the simple Keynesian system happen to be, the flow-of-funds paradigm has unfortunately not yet worked out, perhaps because it was not appropriate in the first place. In the flow-of-funds accounts total sources (total uses) is not the analog of aggregate income and there is no theory how to relate components to predict the total.

The ten chapters of the book are divided into two somewhat unrelated parts. In one part are the initial four chapters, themselves largely unrelated, which are mainly devoted to a presentation of the rationale for having assembled the data. This part of the book also summarizes some of the statistical findings. The other part of the book devotes one chapter to each of the five main postwar capital market instruments: U.S. government securities; state and local government securities; corporate bonds; corporate stock; and residential mortgages.

Chapter 1 is an attempt to evaluate the economic functions performed by capital markets and to describe the main U.S. instruments and institutional participants, using data largely drawn from earlier Goldsmith studies. Chapter 2, labeled "A Framework for Capital Market Analysis," turns out to be devoted mainly to a discussion of the accounting and data gathering problems of constructing a multisector, multiasset set of national flow-of-funds accounts. The framework is little more than a partial set of accounting identities, and, following current fashion, some of them are expressed in symbolic form using algebraic notation. No hypotheses are framed and the accounting framework itself does not suggest any. Moreover, the framework never makes clear what specific problem or problems the social accounts are designed to explain, except perhaps to be the statistical filing cabinet holding the numbers for some vast Walrasian financial system full of "interesting" facts, but lacking the appropriate price and yield data associated with the quantities involved.

Chapter 3, "The National Financing Task: The Volume of Gross Capital Expenditures," presents data in both current and constant prices on the composition of gross and net capital formation over the 1946-58 period classified by principal type of capital good and by acquiring sector. The chapter ends with several interesting tables comparing several trends in net capital formation of the 1946-58 period with earlier periods in American history, some as far back as 1869. Although some of these data are informative and provocative, I have some misgivings about Goldsmith's nomenclature when, in defining his terms at the opening of the chapter he states, "In a closed national economy, the financing task can be reduced to diverting just enough funds from current income to equal total gross capital expenditures on tangible assets which have a length of life exceeding the accounting period of one year and usually set at somewhere around two or three years" (see p. 80). This statement derives from the identity that total uses equal total sources, uses here defined as the sum of gross capital expenditures plus acquisition of financial assets, and sources here defined as gross savings (the sum of depreciation and net savings) plus external sources, all consistently defined. Thus, gross capital expenditures identically equals gross savings plus external sources. In

a closed economy with no government, the identity reduces to the familiar investment-savings identity, which, of course, tells us virtually nothing about aggregate *ex ante* investment decisions, *ex post* capital formation, interest rates, share prices, and so forth. In addition, not only does the terminology suggest some confounding of resource use and financial or accounting practice, but the "task" gives no role to or cognizance of such contemporary phenomena as large-scale consumer credit, government budgetary deficits, and Federal Reserve activities as central bank and as regulatory agency.

Chapter 4, "Internal and External Financing," discusses the financing of capital expenditures in the descriptive context of this form of sources and uses of funds accounting statement, but with more detail for the U.S. economy which is broken down into seven sectors: (1) nonfarm households; (2) agriculture; (3) unincorporated business; (4) nonfinancial corporations; (5) finance; (6) state and local governments; and, (7) federal government. The additional accounting detail includes a finer breakdown of financial uses among short-term, long-term plus equity sources, and also with a separate item for inventory profits.

The fact that the sources and uses of funds accounting statements often include a separate line for capital expenditures does not necessarily mean that the accounting statement *per se* is an efficient means for explaining the volume of investment outlays. In essence, the chapter is a "write-up" of the sources and uses accounting numbers, again in useful historic context, but with little analytical or descriptive relationship to the large and growing body of important studies of capital formation which have been made over the past decade.

The second part of the book consists of one chapter devoted to each of the principal capital market instruments, plus a summary chapter. The specification of the capital market follows conventional lines, so that detailed treatment of such short-term instruments as commercial paper, bank loans, and the like is excluded. Several of these chapters are based on published Postwar Capital Market Study monographs, the Roland Robinson *Postwar Markets for State and Local Government Securities* (Princeton, 1960) and Saul B. Klamman's *The Postwar Residential Mortgage Market* (Princeton, 1960), both of which include much analysis of market behavior as well as a large amount of institutional detail. Goldsmith's attention is primarily directed to the questions of who is issuing what to whom and who is acquiring what from whom. Although these discussions and the accompanying tables and charts pay some attention to institutional detail, the primary emphasis is on recounting the details of the flow-of-funds and national balance sheet accounts. As elsewhere, the emphasis is on quantities; prices and yields receive scant mention, either as causes or effects.

Macalester College

Commercial Bank Behavior and Economic Activity. By STEPHEN M. GOLDFELD. Amsterdam: North-Holland Publishing Co., 1966. Pp. 212. \$7.50.

Professor Goldfeld's book describes a 32-equation, quarterly model of the U.S. economy, estimated on data from mid-1950 through mid-1962. Goldfeld

explains that his primary motivation in constructing the model was to "examine commercial bank portfolio behavior, to relate investment and consumption expenditures directly to financial variables, and to investigate the impact of monetary policy on both financial and nonfinancial variables." Accordingly, Goldfeld first presents a group of equations dealing with commercial banks. These explain changes in bank holdings of excess reserves, borrowed reserves, short- and long-term governments, holdings of tax-exempt securities and the posted rates on commercial and industrial loans. There are separate demand equations for country and city member banks. Goldfeld's disaggregation of free reserves into excess and borrowed reserves and by bank class represents a refinement over earlier treatments. The author finds a speed-of-adjustment coefficient of about unity for city bank holdings of excess reserves and about 0.6 for country banks. Speeds of adjustment for borrowed reserves for both classes of banks, however, remain rather surprisingly slow as they have in earlier studies using a simple stock-adjustment model. It might be noted that Goldfeld's equations for bank holdings of the various kinds of securities do not seem to feed back on the other equations of his model.

A second group of equations seeks to explain quarterly changes in the non-bank public's holdings of coin and currency, demand deposits, time deposits, and in its demand for commercial and industrial loans. There are also two term-structure equations explaining the spreads between bills and intermediate and long-term governments. The nonfinancial sector of the economy is represented by equations for fixed investment, inventory investment, and durable and other consumption expenditures. Other components of GNP are treated as exogenous (as are total private holdings of short and long governments and municipals). The model is closed with the appropriate GNP and banking identities. In the first part of the book Goldfeld experiments with some alternative specifications of the various behavioral equations using ordinary least squares. The final model, which contains a number of nonlinearities, was estimated by two-stage least squares.

The financial sector is hooked into the real sector through the presence of changes in commercial and industrial loans and the long-term government rate (multiplied by current GNP) in the fixed investment equation, and by the presence of the business loan rate and changes in commercial and industrial loans in the inventory equation. The coefficients of these variables are all larger than twice their respective standard errors in the equations finally selected by Goldfeld, and he regards them as "important determinants for both fixed and inventory investment." In addition, the level of the narrowly defined money supply proves significant in the equation for durable consumption outlays. Neither of the final consumption equations contains an interest rate variable. Oddly enough, Goldfeld does not have a separate equation for residential construction, evidently lumping this GNP component in with his exogenously determined GNP residual. Another—less surprising—omission is any attempt to measure the influence of financial conditions on state and local outlays detected by several investigators. In any event, the effects during a given quarter on key endogenous variables of given changes in monetary and fiscal policy variables occurring during the same quarter are derived from the reduced

form of the model linearized at 1962 values of the variables. Goldfeld notes that where comparisons were possible, the results were generally consistent with those of de Leeuw's work in the same vein.

In constructing this model covering a rather large collection of financial and real variables, Goldfeld has had to explore an extensive body of literature in such widely diverse fields as the determinants of member bank borrowings, the market for commercial and industrial loans, and the demand for capital goods. He appears to have done his homework very thoroughly. In the banking field at least, where most of the reviewer's experience lies, he seems to have recognized and attempted to face a remarkable number of the major relevant issues outstanding. Moreover, the author handles the various estimating problems which his model presents with evident finesse and the results in terms of R^2 s, " t " values, and Durban-Watson ratios are generally quite good—though he notes difficulties in applying some of the standard tests to a nonlinear model estimated with two-stage least squares. Finally, the exposition is uniformly lucid. All in all, the book represents an impressive achievement, and anyone interested in the influence of monetary variables on the real economy will want to consult it.

While Goldfeld's work presents an excellent approach to a quantitative treatment of the linkages between monetary and real variables, however, it does not focus much attention on the resolution of existing controversies in this area. One would like to know, for example, why he chose to derive a demand for money function from the Tobin-Teigen formulation rather than from other possibilities that have proved successful elsewhere, or exactly why he gets an important influence of interest rates on fixed investment when some other thorough investigations have not. No doubt a project that would have provided answers to all such questions for a model of the size and complexity Goldfeld constructs would have been an impracticably large task for any single author. Nevertheless, so many conflicting results have been published in some of these areas that a painstaking competitive testing of the outstanding alternatives (together with checks on the robustness of the results in the face of variations in the sample period) would now appear essential if a solid basis for choice is ever to be established.

RICHARD G. DAVIS

Federal Reserve Bank of New York

Mexican Financial Development. By DWIGHT S. BROTHERS AND LEOPOLDO SOLÍS M. Austin: University of Texas Press, 1966. Pp. xi, 236. \$7.50.

Mexico in the past decade has experienced both economic growth and stability, a substantial achievement for any country, and for a developing country located in Latin America it takes on the proportions of an economic miracle. It is no wonder then that this event has been accompanied by the recent appearance of a number of books on various aspects of the Mexican financial system.

This latest book, the result of a collaboration between a Mexican and an American, is divided into two principal parts. The first part is a concise well-written history of the development of Mexican financial institutions and pol-

icies for the period 1940-1960. The second part consists of an analysis of these developments. There is also an introductory chapter on developments prior to 1940 and a brief concluding chapter listing current Mexican monetary problems which is only loosely integrated with the main parts of the book.

The two most striking developments in the Mexican financial structure in the period on which the authors concentrate is the government's decision to shift the financing of the public sector's deficit from the Central Bank to the private financial system and the extraordinary growth of the *financiera* (a type of investment bank). The financing of government deficits with the private financial system helped reduce the inflationary impact of these deficits even though the central bank had to step in from time to time to support the banks and other financial institutions. The important consequences of this change in public debt management policy are only lightly touched upon. The new policy of private government financing resulted in a substantial expansion of the financial system. By largely expropriating the growth in the money supply to finance the deficit of the public sector it reduced the major source of inflationary pressure. The improvement in financial stability however contributed to the increase in the rate of private saving, a large part of which the expanded financial system was able to channel into public and private investment so that part of the increased demand of the public sector for the credit of private financial institutions was offset by increased private saving. The Mexican policy produced a successful type of "forced investment" in the public sector of voluntary saving in contrast to past unsuccessful attempts at financing the public sector through "forced saving."

However, this policy was not an unmixed blessing. To the extent that it was successful the government preempted a larger amount of the resources of an already small capital market than it otherwise would have, had it resorted to an alternative policy of increasing fiscal revenue. Also the larger proportion of private savings channeled through financial intermediaries probably (there are no statistics) resulted in a greater concentration of industry and income because of the close relationship between particular financial institutions and large industrial groups. The greater investment by these large industrial groups and also by the government in capital intensive projects may, in part, have resulted in the reduction in the marginal productivity of capital upon which the authors place great weight in explaining the slowdown in growth at the end of the 1950s. While little is known of how the private sector is financed in Mexico because of the failure of the official financial statistics to identify a private sector as such, it is widely believed that medium and small businesses and farmers were faced with greater credit stringency than other groups in the economy and had to rely largely on self finance.

All the elements of this story are to be found in the book; however, the authors have carefully smoothed off all the rough edges of their arguments which might provoke controversy, and a reader without some familiarity with the Mexican scene may easily miss some key points.

The growth of the private *financieras* is explained largely as a result of the restrictions placed on bank portfolios by the Bank of Mexico through legal reserve requirements. The banks and other groups organized *financieras* which

were free of these restrictions. They could earn a higher yield on their assets and pay a higher rate of return on their liabilities. Their liabilities, being pegged at par and ultimately supported *de facto* by the Bank of Mexico, proved extremely attractive investments in a period of relative financial stability. The exceptional liquidity of the liabilities of the financial system made financial stability not so much a choice as a necessity.

The authors present a convincing model to explain the failure of counter-cyclical monetary policy in Mexico before 1954. They point out that major fluctuations in the level of domestic expenditure were dominated by the behavior of the export sector and that Mexican wealthholders were very sensitive to the risk of devaluation. Any attempt by the monetary authority to offset reductions in domestic expenditure of external origin resulted in an increase in imports and a worsening of the balance of payments. This induced devaluation-fearing Mexicans to take their liquid capital abroad and reduced the level of international and bank reserves restoring the rather stable relationship between the money supply and income.

The authors' explanation of the success of the expansionary monetary policy followed after 1954 is less complete. They believe that the Bank of Mexico came to recognize the limitations set by the process described above and, as a consequence, directed monetary policy toward maintaining internal and external equilibrium and employed selective credit controls and specialized credit institutions to achieve its development objectives. They do not give sufficient emphasis to the change in the government's policy toward private foreign investment and the over-devaluation of the peso in 1954 which yielded a substantial margin of safety in the balance of payments in the following years.

I personally was disappointed by the failure of the authors to bring to light any new data (such as that prepared for the Mexican Development Plan and its evaluation by the Committee of Nine and World Bank), which would remove the public discussion of Mexican financial problems from the realm of speculative economics. The authors rely on well-known sources containing many serious deficiencies which are meticulously described. As partial consolation, however, the book does contain an excellent bibliography on the Mexican financial system.

This reviewer's exercise of his privilege of being critical should not detract attention from the fact that this book by Brothers and Solís is the best general introduction to the Mexican financial system and its development available in English, one that both new and old students of the fascinating Mexican experience can read with profit.

RICHARD S. THORN

University of Pittsburgh

Theorie der Geldpolitik. By ALFRED BOSCH AND REINHOLD VEIT. Tübingen: J. C. B. Mohr, 1966. Pp. 104.

Inflation in world markets, attempts to maintain internal price stability, the preservation of equilibrium in the foreign exchange market with fixed exchange rates, international liquidity, insistence on a full-employment economy, and an autonomous wage structure—these diverse elements bedevil mone-

tary managers and make monetary policy a controversial subject. Perspectives on these problems may differ depending on one's situation. Here we have an excellent presentation of one European point of view, written from the perspective of a country embarrassed by the acquisition of reserves rather than by their loss.

The principal thesis of this book is developed, initially, on two assumptions: namely, that a country produces only internationally traded goods, and that the demand for money is the classical case where the desired cash balances are a certain percentage of the volume of transactions. From the first of these assumptions, it follows that prices are determined on the world market. A country that is small in relation to the rest of the world cannot determine its price level. In every such country there is a certain quantity of money which will bring the balance of payments into equilibrium. Because of the second assumption, this quantity can replace the transactions-balance demand for money. The quantity which results in balance of payments equilibrium is designated by the authors as the equilibrium quantity.

If world prices rise because of inflationary forces outside a country, and if the balance of payments is to remain in equilibrium, the monetary authorities of a relatively small country must increase the quantity of money. Should the quantity of money not increase, then the additional quantity of money necessary for equilibrium will be acquired by the development of an export surplus. Should the monetary authorities create more than the equilibrium quantity, the excess would flow to other countries in the form of a deficit in the balance of payments.

The initial assumptions are later modified by introducing goods which do not enter into international trade, and also international capital movements. These modifications do not, in the authors' opinion, change the essence of their theory. Thus, they conclude that monetary policy determines only the balance of payments, not the price level. Monetary policy has no influence on the level of employment, since the level of employment at the internationally determined price level depends on the wage policies in each of the countries involved. Briefly, the price level is internationally determined; the level of employment determined by wage policies; and the balance of payments determined by monetary policy.

This point of view directly contradicts what is generally considered correct by monetary authorities of the Federal Republic of Germany. In developing their theory, the authors comment on monetary policies in Germany, Great Britain, and the United States. They also state their views on the development of the international monetary equilibrium problem; and they advocate, finally, the creation of an international monetary authority on whom would be pushed the problems that are hard to solve a priori.

This small volume is written with great clarity and simplicity. The thesis is provocative and should stimulate further discussion. German monetary controversies gave rise to the inquiry. On one side of the dispute—if I may put the divergence in its sharpest form—are those who believe that a country should be able to keep its price level stable, even with a fixed exchange rate, in spite of an inflation in the rest of the world. According to this book, an

inflation is "imported" into a country by an excess of exports on the part of the country trying to keep its price level stable. This export surplus may compel the central bank to accumulate foreign exchange and this may increase the liquidity of the commercial banks, expand the quantity of money, and thus lead to inflation. However, if the central bank should compensate for this increase in liquidity, if it should sterilize the additional reserves resulting from additions to foreign exchange holdings, then it should be possible to stop the internal inflation. This is the supposition which, by and large, the German Bundesbank follows. The authors belong to a group which insists upon the direct influence of world prices on the domestic market; and, presupposing, as always, fixed exchange rates, consider as insignificant the ability of the central bank to defend itself against inflation.

Both views probably fail to make a correct appraisal of all the facts. It is an undoubted service to insist upon the fact—which is almost constantly neglected—that an inflation abroad has a direct influence on the domestic price level. This the authors have done; but they may have gone a bit too far. In their own numerical example (p. 22) where domestic goods are introduced into the analysis, it is evident that, in spite of the world inflation, the price level in a small country remains for a long time below that of the rest of the world. This is so even though it is assumed that the quantity of money does increase as a result of the export surplus. The period during which the domestic price level remains behind the world price level can be lengthened considerably, if the central bank manages to prevent the influx of money from having its usual effects. Certainly a country in such a situation cannot preserve a lower price level forever, because the country cannot afford to put at the disposal of other countries a constantly increasing surplus of exports; nor can the central bank over a long period prevent the expansive effects on the monetary system of export surpluses. For a considerable period of time, however, the restraint exercised by a country's monetary authorities can succeed; and a country has, besides, an influence in damping world inflation through the repercussions which arise when it draws to itself international reserves.

The authors of this book do not deny the points here raised in criticism of their thesis. They weigh the factors differently; and, in expounding their principal argument, minimize the significance of these factors. The two extreme positions on this matter can be unified into one more general theory, *if* one separates the short-run point of view from the long-run. Then the proposition of these writers that one country must acquiesce in a world wide inflation can be designated as the long-run point of view.

RICHARD C. BERNHARD

University of Utah

Money, Banking, and the Economy. By JOHN A. COCHRAN. New York: Macmillan, 1967. Pp. xvii, 605. Prob. \$8.95.

There is relatively little that one can say about a competently done undergraduate text; thus, the reviewer is forced into one of the three major varieties of "reviewermanship." The first, and clearly the most satisfying, is to mount a

vicious attack upon the author's lineage, sobriety, and competence—concluding the review with a single pithy epithet, aptly chosen to doom the book and the author. The second is to demonstrate vast patience and scholarship by counting misspelled words, improper usage, faulty footnotes, etc. The third is to compare the book at hand with the one the reviewer would have written, had he the inclination, or the time, or the necessity. I shall endeavor to unite these three approaches within the constraint so cruelly imposed by the length limitation.

The issue is, of course, whether there are important reasons to prefer Professor Cochran's text to the others in the field. On balance, Cochran's book will be a sound competitor. The historical and institutional material is superb—the second and third chapters efficiently dispose of what we need to know about the history of monetary standards and the current American standard. The next seven chapters deal with commercial banking questions; they are well organized, well written, and very much up-to-date. However, of particular interest are the next three chapters, a section on money and the capital markets. Chapter 11, entitled "Flow of Funds in Financial Markets: Sources and Uses of Funds," presents a concise and competent summary of the mysteries of that social accounting system and Chapters 12 and 13 do a fine job on the money market, bringing out forcefully recent innovations of importance. In short, the first half of the book is good, possibly excellent.

The main problem arises in Parts IV and V—dealing with "Central Banking" and "Monetary and Income Theory." Chapter 15 in the former section deals with Federal Reserve credit and commercial bank reserves and, in my opinion, emphasizes and details the wrong things. Perhaps it is true that the contributions of Meigs, Brunner and Meltzer, Polakoff, Dewald, and others need not be treated in an elementary text on monetary economics (I think they should be), but at the very least they should be mentioned in selecting a bibliography for further reading. Instead, Cochran treats the serious student to seven references to bank reviews. Cochran also gives us a rather confusing picture of member bank borrowing. On the one hand, when "... the discount rate is markedly below the short-term Treasury bill rate, it might seem apparent that the Federal Reserve might be trying to encourage member banks to borrow..." (p. 294). On the other hand, member banks "... are supposed to feel themselves under pressure when they are borrowing..." (p. 290). A straightforward introduction of the "profit" and "reluctance" hypotheses, along with the admission that current empirical work has not yet sorted out the two effects very well, would have been preferable. Also, the discussion of the effect of discount rate changes on market expectations lacks precision.

The role that money plays in national income analysis is treated in one short chapter (Ch. 17). Despite the fact that such material as short-run vs. long-run consumption functions and the "super-multiplier" is introduced, the chapter omits presentation of a simple Keynesian equilibrium—yet, question four on page 338 asks something about the LM schedule, nowhere explicitly introduced. Although it probably is true that Keynesian comparative statics is adequately covered in most principles texts (and, we hope, courses), considerably more could be expected in a money and banking text—for example, some

of the recent econometric work on the demand for and supply of money could usefully be introduced at this point (or in Ch. 20, "The Quantity Theory of Money Revisited").

The dust jacket says that "economic growth is given particular attention." This statement presumably refers to Chapter 18, which is entitled "Economic Growth." Harrod, Domar, and Rostow are discussed, but this seems out of place in a book devoted to monetary matters. The only thing that the monetary authorities must do in this connection, apparently, is to decide "... how much reserves to furnish to the banking system in order to permit a certain rate of growth in the money supply ..." (p. 339). We do not, unfortunately, have much more to say in this neglected area, but it seems to me that one need not "drag in" the topic if that is the case.

The last part of the book deals with various public policy issues and is exceedingly well done. Chapter 23, on "Fiscal Policy and Debt Management" explains the three types of government budget clearly and concisely and raises a number of salient questions about the management of our ever-expanding public debt. Chapter 24 discusses the public policy proposals of the Commission on Money and Credit, a welcome resuscitation of moderate reform proposals that have largely been ignored. Chapters 26 and 27 deal with international monetary questions and institutions and Chapter 28 raises some "final questions" about "Money and Banking in an expanding economy."

In summary, Cochran has written a text that deserves serious consideration for the elementary monetary economics course. It will probably be selected by those who wish to stress institutional material; it is probably the best available text from that point of view. There are also other favorable selling points, but the paucity of theoretical material is a serious shortcoming. In closing, since Cochran opens each chapter with a selection from *The Wealth of Nations*, let me say: "... I am always willing to run some hazard of being tedious in order to be sure that I am perspicuous; and after taking the utmost pains that I can to be perspicuous, some obscurity may still appear to remain upon a subject ..."

GEORGE J. VIKSNINS

Georgetown University

Public Finance

Effects of Corporation Income Tax: Papers Presented at the Symposium on Business Taxation. Edited by MARIAN KRZYZANIAK. Detroit: Wayne State University Press, 1966. Pp. 268. \$8.95.

Of the numerous uncertainties that plague fiscal economists, few can rival that concerning the incidence of the corporation income tax. The second most important tax in the country, it is believed by some to burden corporations and their shareholders while others argue that it is largely, or entirely, shifted forward onto consumers or backward onto workers. Nor is this the full extent of expert disagreement. In their 1963 econometric study [9], Marian Krzyzaniak and Richard A. Musgrave suggested not only that corporate tax increases

tend to be overshifted but that corporate tax decreases may be significantly undershifted. This raised the intriguing prospect that corporate stockholders could become better and better off if only they could persuade an understanding legislature to keep raising and lowering their tax rates at suitable intervals of time. Such startling results were not likely to remain undiscussed for long, and the volume of papers under review here is the first in what may well be a long line of studies dealing with the incidence of the corporation income tax. In it the policy-maker will find only a few, rather tentative, answers, but the economic researcher will want to consider seriously many of the points made before embarking on his own analysis of the effects of the corporation income tax.

In the leading and longest paper in the book Krzyzaniak skillfully manipulates four long-run, neoclassical growth models, using Cobb-Douglas and CES production functions to determine the impact of both general and partial profits taxes on the rate of return earned on capital and on the share of profits in total national income. The analysis begins with a useful section on "Indicators and Measures" (pp. 25-29) in which precise definitions of different degrees of tax shifting are derived, and throughout the subsequent discussion careful attention is paid to the sensitivity of the shifting process to different values of the important economic parameters, such as the elasticities of substitution between factor inputs and, in the case of a partial profits tax, between the products of the taxed and nontaxed sectors of the economy. The results, which indicate a high degree of shifting in the long run resulting from a tax-induced decline in saving and investment, are difficult to evaluate, however, because of the patently unrealistic assumptions made in the mathematical models. Moreover, everything depends on the nature of the impact of profits taxation on incentives and abilities to invest, and, because of the long-standing work of Domar and Musgrave [1, 10] and the more recent analyses of Hall and Jorgenson [3, 4], one may question Krzyzaniak's basic assumption that profits taxation necessarily does depress society's saving rate. Be this as it may, it is interesting to note the extreme slowness with which the shifting process operates in the models discussed. It would be a far-sighted politician (or statesman) indeed who would be seriously concerned with economic effects that required 40-50 years to achieve as much as one-half of their full potential, and over 100 years to reach 90 per cent of it!

In a short paper drawing on theoretical and empirical work that he and his associates have published, or are about to publish, elsewhere [5, 6, 7], Harberger derives a rough, quantitative measure of the efficiency loss resulting in this country from differential intersectoral tax rates on income from capital. Simplifying an exceedingly complex situation into one involving only a highly-taxed, mainly corporate, sector with an average 1953-59 tax burden of 62.7 per cent of gross income and a lightly-taxed, mainly noncorporate, sector with a 1953-59 tax rate of 31.0 per cent, Harberger estimates that this tax differential induced a 17-30 per cent capital outflow from the corporate sector (i.e. a decline in the capital stock from \$23.5-\$27.5 billion to \$19.5 billion), which in turn imposed an efficiency loss lying, to take his most probable case, between \$1.5 and \$2.5 billion a year. These findings, tentative as they are,

constitute a welcome innovation in this area of tax analysis. Future research may confirm or deny the existence of a relatively large tax-induced shift of capital into such industries as oil and gas, residential housing and agriculture (Krzyzaniak himself makes an inconclusive attempt in a long footnote on pp. 50-51 of his paper), but in the meantime Harberger's analysis reinforces the importance of knowing more than we do about factor and product elasticities of substitution and about the effects of disaggregation on the sizes of efficiency losses (or gains) from resource reallocations.

Another short paper, by Musgrave, presents a taxonomic analysis of the "Effects of Business Taxes Upon International Commodity Flows" that points up some of the costs of our present uncertainty concerning the incidence of production, consumption, and profits taxes. If these are shifted forward to consumers, neutralizing fiscal adjustments may be desirable to offset the effects on commodity flows of production and corporate profits taxes; if, on the other hand, tax burdens remain on, or are shifted backward to, factor incomes, both profits and general production taxes would be neutral in their impact on commodity flows. Unfortunately, as Musgrave notes, rigorous empirical tests of these conflicting propositions are still very much in their infancy, and as a consequence trade policies are likely to remain controversial for some time to come.

The remainder of the book—some 125 pages—is devoted to a critical evaluation of the Krzyzaniak-Musgrave (hereafter K-M) study of corporate tax incidence [9] by Richard E. Slitor and Richard Goode, including a defense by K-M and a rejoinder by the two critics. It has been some time since a debate of this sort has enlivened the pages of fiscal economics, and though no final answers are provided, many valuable guidelines for future studies are laid down. The attack on the K-M doctrine that increases in the corporate income tax are overshifted in the short run is developed along three major lines. The first involves a severe, and on the whole, convincing, criticism of the validity of the K-M theoretical model. Goode notes that one of the dependent variables, the rate of return on corporate capital, is subject to large errors of measurement which may have a significant effect on the empirical estimates obtained, and both Slitor and Goode complain about the imprecision in the definition of the variable used to measure effective tax rates. By including excess profits taxes in its numerator and the losses of deficit companies in its denominator, they argue, the tax variable fails to isolate the rate changes that can logically be expected to induce corporate attempts at tax shifting. Still more disturbing, however, are the questions raised concerning the three nontax independent variables used in the basic K-M model. To Slitor the prior-year change in the ratio of consumption to GNP is only a "pseudo-accelerator," and Goode wonders why, if the variable does represent the acceleration principle, it was not defined as the ratio of the change in consumption to GNP, or as the rate of change in GNP or in some other general measure of economic activity. The second independent variable, the prior-year inventory to sales ratio in manufacturing, is a plausible measure of the pressure of costs on profit margins, but, understandably, Goode concludes that ". . . on economic grounds, the one-year lag is curious" (p. 214). The third variable, the current-

year ratio to GNP of federal, state, and local noncorporate taxes, minus government transfers to domestic recipients and grants-in-aid to state and local governments, is perhaps the most perplexing of all. On the one hand, it might represent the impact of rising (or falling) governmental operations on profits and hence have a positive coefficient, and on the other, it might reflect the negative influence on corporate profits of higher noncorporate taxes, government expenditures being taken as given. In the K-M study it is the latter result that apparently emerges. All in all, it appears that the K-M theoretical model emerges from this attack badly shaken, if not largely demolished.

The second major criticism of the K-M study is based on the familiar econometric problem of multicollinearity. Have K and M, the critics ask, really isolated the effects of the tax variable from the effects of those other variables that influenced corporate profit rates during the period of analysis and were also correlated with corporate tax rates? Is not the estimated size of their tax rate coefficient highly sensitive to the specifications of the empirical model? On neither question is there a meeting of the minds of the disputants. Slitor does test the validity of his criticisms by using an "economic pressure" variable (the Knowles ratio of actual to potential GNP [8]) to supplant or supplement the independent variables used by K and M in their basic model, but the results he obtains, indicating a drop in the shifting measure from 134-141 per cent to 87-99 per cent, are ambiguous. They do, to be sure, show a considerable degree of instability in the shifting coefficient, but they do little to refute the K-M conclusion that the corporate profits tax is fully shifted in the short run. In addition, the disputants argue inconclusively over whether or not inclusion in the model of an unlagged pressure variable creates a simultaneous-relations problem and hence results in biased statistical estimates.

The final set of criticisms concerns the plausibility of the K-M findings. To Slitor shifting on such a scale ". . . long- or short-run, defies credulity" (p. 167), and Goode finds it hard to believe, as do I, that had corporate tax rates remained constant between 1936-39 and 1955-57, the before-tax rate of return on the total capital of manufacturing corporations would have *fallen* between the two periods. Yet the K-M model predicts, for example, that if 1955-57 tax rates had applied in 1936-39, the before-tax rate of return would have been 16.66 per cent, compared to an actual rate of 7.46 per cent in 1936-39 and one of 16.33 per cent in 1955-57 (p. 217). Similarly unorthodox is the K-M "ratchet effect" under which profits tax changes fail to reduce corporate income on the way up but do augment it on the way down. The latter finding, however, is based on a single, and rather special, statutory tax rate decrease—the pre-announced removal of the Korean excess profits tax in 1954—and hence, in the words of Slitor, ". . . it hangs by a statistical thread" (p. 171). Another aspect of the general plausibility test concerns the "price umbrella" effect that is implied by full and rapid shifting of corporate tax increases. Here the argument is that profitable firms, by increasing their sales prices and gross profit margins in order to shift the tax, will provide inefficient firms with a better economic environment in which to continue to operate. Slitor tests this hypothesis by relating changes in the relative size of the deficit corporation group in manufacturing to tax rate changes for four periods between

1926-29 and 1957-60 (pp. 179-83). The results, however, are inconclusive because of uncertainty as to how much of the negative correlation found should be attributed to the tax rate changes rather than to other factors.

Perhaps the chief contribution of the original K-M study and the critical discussion of it in this book will be the stimulus provided to other researchers. Evidence to this effect is already available. A study by John G. Cragg, Arnold C. Harberger, and Peter Mieszkowski, prepared for a Brookings volume on "The Taxation of Income from Capital" [7], deals imaginatively with both the collinearity and the simultaneous-relations problems and emerges with statistically insignificant coefficients for the tax rate variable. Using a fully articulated theoretical model and sophisticated statistical estimation techniques in a paper to be published in this journal [2], R. J. Gordon also finds no evidence of corporate tax shifting in the short run. What one believes about this phenomenon, therefore, depends largely on which econometric analysis, if any, he regards as definitive. The only safe conclusion is that there will be many more attempts to unlock the enigma of the corporate profits tax.

Federal Tax Policy. By JOSEPH A. PECHMAN. Washington, D.C.: The Brookings Institution, 1966. Pp. xxi, 321. \$2.45.

This book is intended for the "interested citizen." The citizen would have to be interested indeed to work his way through the detailed descriptions of each tax, the arguments for and against proposed changes, and the vast

amount of historical and statistical material. The greatest beneficiary of the volume is likely to be the writer of economics textbooks. The graduate student will be a close second, especially in view of the extensive bibliographical notes. All authors will look with envy on the carefully drawn charts and tables. Apart from anything else, this book proves conclusively that a large quantity of research funds will produce a large quantity of research.

Taxation economics can be no better than the theoretical structure on which it is built, whether implicitly or explicitly. In studying this book one gets an uneasy feeling that the economic analysis—the underlying “model” one might say—does not form an interconnected whole but is rather based on bits and pieces that have been accumulated over the past three decades without adequate attention to gaps and inconsistencies.

There is a tendency to make a dramatic generalization that is incorrect as it stands and then mention various qualifications and modifications which, if properly digested and integrated, would undo most of the damage done by the generalization. Can we impose so heavy a burden on the interested citizen or even the professor and student? In the discussion of saving and investment, for instance, we are told that budget surpluses at full employment contribute toward increasing the investment rate (p. 22). Surely it depends on what kind of taxes produced the surplus, what is done with the surplus, and what kind of taxes and expenditures constituted the rest of the budget. The author has previously pointed out the importance of the composition of expenditures and taxes (p. 20) and later mentions the need to “avoid taxes that impair investment incentives” (p. 23). All this is like saying, “Two plus two equals five except that it really equals four.”

In the summary of the same section, the author says, “At any given level of government expenditures, the level of economic activity depends on the *ratio* of taxes to expenditures” (p. 29; emphasis in original). Again, the specific nature of taxes and expenditures is ignored. And again, after the damage is done, we are told, “Saving and investment incentives may also be improved through higher depreciation allowances, investment credits, and other structural tax provisions” (p. 29). It is as if there were two opposing bodies of thought fighting for control and both were declared winners.

In considering the effects of balanced changes in expenditures and taxes, the author first presents a hypothetical analysis in which, by restrictive assumption, expenditure changes are allowed to have greater multiplier effects than tax changes (pp. 10-11). Reference is also made to the important role of monetary policy (pp. 11-12). Then qualifications are forgotten and we are told that expenditure changes have somewhat larger multiplier effects than tax changes (p. 13). The balanced budget fallacy thus persists. The outcome will actually depend on the detailed nature of the taxes and the expenditures and on the state of the capital market, to say nothing of the propensities of those affected. It cannot be said in general that spending will be more expansive than an equal reduction in taxation.

The author asserts that debt created under conditions of excessive unemployment “cannot be a burden on future generations” (p. 26). There are two sides to this question and neither side is represented adequately in the two-

page discussion. It would be better to omit this topic from a book on tax policy than to do less than justice to the significant contributions of recent years. Silence might have been better than brevity in this case.

The 1964 tax cut is reviewed and we are told, "The economic potency of tax cuts has thus been firmly established" (p. 9). A lot more than one successful case is needed before any sweeping generalization can be made as to what is "firmly established" empirically.

The author refers to the fact that "corporations have been able to increase their before-tax profits enough to avoid a reduction in the after-tax return, without increasing their share of income in the corporate sector" (p. 108). He then says, "These observations suggest that corporations have not increased rates of return before tax by marking up prices or by lowering wages, but by making more efficient use of their capital" (p. 108). But the macro data on income shares are based implicitly on price-times-quantity and on wage-times-quantity, not on prices and wages alone. Depending on the relevant elasticities, the macro data are entirely consistent with price and wage changes. Moreover, if price, wage or efficiency is changed as a result of an income tax, profit was evidently not being maximized before the tax was imposed (or raised). There is no reason to believe that price and wage policies were optimal and only efficiency could be improved. The same motives and conditions that prompted changes in efficiency would prompt efforts to change the other variables.

Of the many important questions of tax policy discussed in this book, we may refer to two: greater use of the sales tax and adoption of a shared-revenue plan to help the states. Speaking of proponents of general consumption taxation, the author tells us, "Their concern is to reduce progression, . . ." (p. 160). Two other positions in favor of general sales taxation exist. One of these looks at the tax-expenditure structure as a whole and sees that the net effect of expenditures, though financed by sales taxes, is (or could be) favorable to low- and middle-income groups. Refusal to adopt a sales tax which would make possible the spending (that would not otherwise occur, it is assumed) is actually inimical to the interests of these groups.

The other position that is favorable to sales taxes is that they can actually constitute a progressive element in the tax structure as a whole. The exemption of food and medicine substantially removes regressive aspects; and the tax extracts some contribution to public services from those who manage somehow, legitimately or illegitimately, to maintain a high standard of living and yet pay little or no income tax. A sales tax of this sort can supplement the income tax in ensuring the progressivity and equity of the revenue framework. That the income tax could use some help is suggested by the author's own figures (p. 256) which show \$34.8 billion of nonreported adjusted gross income in 1963, only part of which would be nontaxable if reported, and \$61.2 billion of personal income not includable in adjusted gross income because of conceptual differences.

At the state level, the author emphasizes the need for a credit against state income tax to remove the regressivity of the sales tax (pp. 161, 211). As suggested above, however, a good case can be made for the sales tax even in the

absence of a credit. Moreover, the sales tax need not be at a flat rate; it could be designed on a graduated basis with higher rates applying to big-ticket items.

A basic defect of the empirical analysis of regressivity is that current income is used as the sole measure of ability to pay (pp. 50, 150 ff.). No allowance is made statistically for assets or income beyond the current year although the possible significance of such allowance is mentioned (p. 154). Some persons who are retired or are between jobs may have large assets or income over a longer period and could help pay their fair share of governmental costs even this year. The intellectual resistance to inclusion of assets is well illustrated by a query posed by the author in the context of the negative income tax: "Should assets of the needy families as well as their income be taken into account?" (p. 75). But how can we label them "needy" before we look at their assets? If they happen to have large assets are they "needy"? It is hard to understand why those who pride themselves on being concerned with equity are reluctant to incorporate longer-term income or wealth in their measurement of the ability to pay current taxes.

The book ends with a strong plea for what has become known as the Heller-Pechman plan for unconditional grants to the states based on shared revenues. Pros and cons are given but the major defects of the plan do not stand out.

Any grants tied to a fixed percentage of the federal income tax revenues would be procyclical and would get more money to the states in prosperity than in depression. A trust fund or a variable percentage, if used, would introduce the element of discretionary authority and its political and economic complications. At best, the plan makes no contribution to the much-needed improvement of state tax structures and the elimination of multiplicity of tax forms and tax provisions. One is reminded of the episode in the musical *Call Me Madam* in which the Prime Minister of the mythical Duchy of Lichtenburg refuses to accept a large American loan because it would make unnecessary the basic economic reforms he had been advocating for years.

The author states that included among the opponents of the revenue-sharing plan are "those who . . . have little faith in the willingness or ability of state governments to use the funds wisely, . . ." (p. 229). From this we may infer that proponents of the plan have much faith in the willingness and ability of the state governments to use the funds wisely. They do not have a monopoly on such faith, however, among those who are seeking to solve the fiscal problems of federalism.

An alternative to the revenue-sharing plan is a thoroughgoing tax credit scheme. All state and local taxes would be credited against federal income tax liability up to a certain percentage of state and local taxes (or other limitation). The credit could be given immediately as in the case of unemployment insurance taxes (hence, we may call it an "instant tax credit") thereby avoiding liquidity problems for the taxpayer. And there could be inducements to achieve conformity and interstate uniformity in matters of detail. The states would not only spend the money themselves, they would raise it themselves. This puts the tax credit plan doubly on the side of the angels.

As may be expected, there are very few factual errors in a book that was

read in full by 13 tax experts and in part by 28 more. A few misleading or incomplete statements have crept in. They are mentioned here because of the possibility that the volume will be used as a book of reference on tax provisions and that the errors will find their way into other books and perhaps even articles in learned journals.

The author says, "In 1964, the [dividend] exclusion was raised from \$50 to \$100 (\$200 on joint returns)" (p. 138; similarly, 134, 238). The filing of a joint return is not sufficient to ensure a \$200 exclusion though dividends be ample. Husband and wife must each receive \$100 in dividends in their individual names or in their joint names to ensure the maximum exclusion.

We are told that "fewer than ten shareholders" are required for partnership treatment (p. 138). The requirement is "no more than ten." The tenth man is in.

Reference is made to the fact that, "Gains on the sale of owner-occupied houses are exempt if they are applied to the purchase of a new home within twelve months" (pp. 90-91). But if the new home is newly built there are eighteen months allowed after the old house is sold.

Under the 1948 law, we are told, "Half of all inter-spousal transfers was eliminated from the bases of the estate and gift taxes" (pp. 184-185). This is misleading as to estate taxes. The author himself mentions at several points that the marital deduction in the estate tax is *all* that is given to the spouse, up to a limit equal to half the estate.

"Income in kind" is listed as one of the categories of personal income not included in adjusted gross income (p. 256; also, 260). In fact, some forms of income in kind are included in adjusted gross income. One of these is pay received in property instead of cash. The employee must report the fair market value of the property as wages (except in the case of Christmas turkeys).

The excess profits tax of World War II is stated as having been as high as 95 per cent (p. 238). This is true but there was also a provision for a rebate of 10 per cent of this.

Finally, in quoting the Sixteenth Amendment, the author (or typist) incorrectly uses the singular of "taxes" and the plural of "source" (p. 236).

There is no use making a federal case out of all this even though many a federal case has been made out of much less. The errors are minor. The 41 tax experts whose help is acknowledged should not sue; nor should they be sued.

HAROLD M. SOMERS

University of California, Los Angeles

Tax Reform and the Alliance for Progress. By RAYNARD M. SOMMERFELD. Austin: University of Texas Press, 1966. Pp. xiv, 217. \$5.00.

Since World War II the newest and possibly the fastest growing field of public finance is the formulation of appropriate tax policies for the underdeveloped countries of the world. Despite the growing volume of professional literature dealing with particular issues and countries, and despite also the increasing number of conspicuously good scholars undertaking research in this field, no one has had the temerity to write a comprehensive study comprising

both theoretical and applied aspects of tax policy in underdeveloped countries. Even though Sommerfeld has limited the scope of his research to Latin America, the task still remains much too ambitious. He would have been well advised to have tried something less demanding.

The monograph has a pragmatic purpose. In the absence of detailed fiscal studies of each Latin American country, the author has attempted to suggest guidelines for tax-reform efforts which would serve the goals of the Alliance for Progress. Appropriately, he begins, after an introductory chapter, with an examination of the three basic documents establishing the framework for the Alliance in order to obtain directives in the form of tax policy goals. Unfortunately, however, these documents were written by bureaucrats and politicians rather than by social scientists, with the result that some tax policy goals are either not mentioned (e.g. efficiency in the utilization of resources) or they are couched in meaningless terms unless translated into their precise tax policy equivalents (e.g., "demanding more from those who have most" is actually a mandate for an optimum distribution of income). When Sommerfeld fails to identify and discuss the policy goals which are implied but inadvertently omitted from the Alliance documents, and when he discusses the other goals superficially (stability is considered to be only a problem of price stability), the result is that his study has no sound theoretical frame of reference. Without having a clear rationale for tax reform, it is quite impossible to make recommendations for improvement that are consistent, logical, and purposeful.

After this haphazard discussion of tax policy goals, the author presents a chapter dealing with some general characteristics of Latin American tax systems—the level of taxation, relative importance of direct and indirect taxes, tax sharing, and the widespread tendency in Latin America to earmark tax revenues. About one-half of the remainder of the book is concerned with particular taxes (individual chapters on income taxation, wealth taxation, and other taxes), while the other half includes chapters on tax-exemption schemes, tax administration, and a summary of findings and recommendations.

While the failure to develop a sound framework for tax policy design is the principal shortcoming in this study, there are several other faults that detract from the monograph's serving its purpose as a guide for tax-reform efforts in Latin America. Although customs duties are the most important single source of tax revenue in most Latin American countries, and appropriate tariff policy one of the most crucial issues of tax reform, this subject is summarily discussed (in about two pages) with the observation that "Very little useful generalization can be made about tax-reform efforts in regard to customs duties since these taxes are frequently imposed for trade control, and only secondarily for revenue purposes" (p. 127). Although one of the principal sources of income tax revenue is corporations, and this revenue is of strategic importance for the allocative function of providing resources for public investment purposes, an elimination of the double taxation of corporate income is recommended (p. 80). Although monopoly influences are pervasive in Latin America, and this problem is often exacerbated by the prevalence of windfall gains due to inflationary pressures and frequent monetary devaluations, the abolition of excess profit taxation is recommended (pp. 131-32). One would hope

that Latin American countries would not take too seriously the advice also given that they should consider a poll tax (p. 133). In the light of these and other deficiencies, it would be superfluous to elaborate on the errors of fact, the use of secondary sources, and the spotty bibliography.

With some foreboding, Sommerfeld observed at the outset of his study that "It is only hoped that this work will not be obsolete before the last pages are written." Unfortunately, this too has happened to some considerable degree. In the early days of the Alliance, it was realized by the Joint Tax Program of the Organization of American States, the Inter-American Development Bank, and the Economic Mission for Latin America that the countries of Latin America would require broad fiscal policy guidelines to accomplish the economic goals set forth in the Charter of Punta del Este. For this purpose a conference was convened in 1962, at which the luminaries of the public finance world addressed themselves to all the major issues to be faced in restructuring the revenue systems of Latin America. Although these papers were not published until 1965,¹ mimeographed copies of the conference proceedings were distributed in Latin America as early as 1963, three years before Sommerfeld's book was published.

Lest it appear that this reviewer is being too harsh in his criticisms, it would be well to conclude with a few observations on the prerequisites for a successful completion of the assignment Sommerfeld set for himself. Since probably the paramount goal of tax policy in Latin America is economic development, one must have somewhat more than an incidental knowledge of the processes of economic growth and how development can be induced in underdeveloped countries. Since tax policy is interrelated with fiscal policy, with monetary policy, and in fact to some degree with every facet of economic policy, one must be as much an economic generalist as a specialist in public finance. All of this technical equipment would not be sufficient, however, unless it were combined with a wealth of institutional knowledge of Latin American social and economic conditions, and there is really no way to obtain this except by field research over an extended period of time. One must also be prepared to work with skimpy and unreliable statistics, with documents that are in a foreign language, and with material that is seldom available to the public. Little wonder under all of these circumstances that Sommerfeld fell short of his target.

MILTON C. TAYLOR

Michigan State University

¹The Joint Tax Program of the OAS, IDB, and ECLA, *Fiscal Policy for Economic Growth in Latin America*. Baltimore 1965.

Income Distribution and the Federal Income Tax. By BENJAMIN A. OKNER. Michigan Govt. Studies No. 47. Ann Arbor: Institute of Public Administration, The University of Michigan, 1966. Pp. xiii, 148. \$3.00.

Professor Okner has added to our general knowledge of the redistribution accomplished by the federal individual income tax. By means of computer simulation performed with a subsample of 1962 income tax returns, he has

broken new ground in quantifying the redistributive effects of the numerous provisions, including the tax rates schedule, of the tax as it exists. He has been able to develop "before and after" Lorenz curves for the present tax law, the pre-1964 tax law, and each of the outstanding features of the law such as the exclusion of certain forms of income from the tax base, the deduction of certain expenses, and the exemption of a certain amount of income per person. He concludes by computing the shift of income that would follow from adoption of what he considers a more nearly ideal definition of a tax base. (This is referred to below as the Okner reform.) The principal findings are summarized in the accompanying table, which is set up to show possible deviations from the norm of the 1964 Revenue Act.

| Change in Tax Law | Percentage Increase (+) or Decrease in After 1965 Tax Area of Inequality | Share of After Tax Income of Tax Filing Units with Total Income | |
|---------------------------------------|---|---|-----------------------|
| | | Under \$3000 | \$500,000 and Over |
| Change to regressive tax rates | a | a | a |
| Abolish income tax | +17.70 | 7.694 | b |
| Change to flat rate of 19 per cent | + 1.83 | 8.072 | .707 |
| Abolish personal exemptions | + 1.12 | 8.031 | .609 |
| 1964 Revenue Act | 0.00 | 8.158 | .579 |
| Return to 1963 tax law | - 0.05 | 8.204 | .581 |
| Introduce negative tax rates | - 0.97 | 8.501 | .577 |
| Increase level of personal exemptions | a | a | a |
| Disallow all nonbusiness deductions | - 1.11 | 8.265 | .525 |
| Abolish all exclusions | - 1.47 | 8.292 | .336 |
| Eliminate income splitting | - 1.67 | 8.294 | .585 |
| Adopt Okner reform | - 3.27 | 8.454 | .283 |
| Use total income as tax base | - 4.26 | 8.411 | .286 |
| Change to more progressive tax rates | a | a | a |

Sources: Column 1, text tables and derivations from data cited in text of book under review. Columns 2 and 3. Appendix Tables E-1 through E-5, *ibid.*

(a) Not discussed in book under review.

(b) Not available.

It shows, for example, that substituting a flat rate of 19 per cent for the present set of progressive rates would increase income inequality by 1.83 per cent; it would reduce low-income taxpayers' share of income only slightly, but would increase high-income taxpayers' share of income by 22 per cent. On the other hand, the table shows that using total income as the tax base would reduce after-tax inequality by 4.26 per cent and cut the top group's share of income by almost one-half. The table shows the direction of the effect and relative significance, as far as redistribution is concerned, of several possible changes in the law as set forth by Okner. I have also listed in the table three types of changes that he did not consider.

The tax structure, as now designed, has some benefits for everybody. As Okner points out (p. 76), it has personal exemptions for the low-income groups, nonbusiness deductions and income-splitting for the upper-middle income people, and special capital gains provisions for the rich. After reviewing the nature of and the rationale for these provisions in detail, Okner concludes that considerations of equity dictate a wholesale reform of the tax base. He would include full capital gains, imputed rent, social security benefits, and presently tax-exempt interest in the base, scrap the optional standard deduction, and disallow deductions for interest paid and taxes other than state income and sales taxes. He would replace the present scheme of personal exemptions with a \$150 per person tax credit. By means of such a reform he would reduce income inequality by 3.27 per cent. (See table.)

While the import of the simulation effort was to produce the detailed quantifications summarily reviewed above, the main arguments for and against the Okner reform are not those concerned with vertical redistribution, but rather those having to do with horizontal equity, which is not so easily quantified. It is often stated, but seldom observed, that vertical equity measures presume that horizontal equity is already accomplished. Following this logic, Okner defines his inclusive tax base to achieve what he regards as horizontal equity and then is pleased to discover that it would produce as a by-product more redistribution toward equality than does the present tax base. He does note that the reform would enable considerably lower tax rates to raise the same revenue, but he makes no claim that lower nominal rates are in themselves important.

So far as horizontal equity is concerned, Okner contributes little that is original, although he does provide succinct reviews of the literature on each tax provision. As we have noted, he does add to the quantitative dimension of knowledge concerning vertical equity. However, it seems to me that to complete his study, he should have asked several additional questions. First among them is: what re-ranking of taxpayers might follow from various reforms? Is it not likely that methods of reporting and realizing income will change with the tax law? Okner makes no mention of responses that high-income families might make to a decision to eliminate income-splitting or to remove the special treatment now accorded capital gains. In other words, he ignores the fact that the pre-tax distribution itself is to a certain extent an artifact of the existing tax system.

A second question that would have been worth asking, and one that certainly lends itself to simulation, is the following. How much does the vertical redistribution resulting from a given tax law depend upon the per capita level and inequality of pre-tax income? A third but more difficult one to deal with is: what difference in redistribution would follow from adopting a tax accounting period of more or less than one year?

A fourth question that needs to be taken up involves varying the definition of the income-receiving unit and asking what the relationship is between the tax unit and the family unit under different possible tax provisions. There is only limited meaning to a ranking, without regard to the size of the unit, of families and sub-families represented by tax returns. There would be more

value in knowing the distribution and redistribution within a standardized family size group. Along this same line, it needs to be noted that because the author took no account of the 15 per cent of persons not represented on income tax returns, he was unable to give more than a page of vague speculations to one of the more interesting proposals to expand the redistributive effect of the income tax, namely, the reverse or negative income tax.

While Okner has not dealt with all the questions implied by the title of his book, he has taken advantage of early access to a primary data source and of competence with computer technology to provide us with valuable insight into some significant relationships between the income distribution and our leading tax. For that, he has put all public finance students in his debt.

ROBERT J. LAMPMAN

University of Wisconsin

International Economics

Le développement d'un marché européen des capitaux. Rapport d'un Groupe d'Experts constitué par la Commission de la CEE (European Economic Community, *The Development of a European Capital Market, Report of a Group of Experts appointed by the EEC Commission*). Pp. xlii, 408. Brussels: European Economic Community, 1966.

In 1950 or 1951 after the proposal of the Schuman Plan I suggested in a lecture that functional integration, by commodities or through customs union, was likely to be a half-way house in which the Six could not dwell long. Either they forged ahead and achieved wider economic union, possibly going so far as to merge their economic sovereignties, or they would probably slip back into national policies carried out independently. In particular it seemed to me that employment, wage, price, tax, and foreign-exchange policies could not be carried out separately while a significant number of or all commodity and factor markets were joined.

This may or may not have been a correct forecast, depending upon whether 17 years is a long time. Integration has broken down in coal policy, but it has survived the devaluation of the French franc in 1957 and 1958 and the revaluation of the guilder and Deutschmark in 1961. And harmonization has been proceeding. It has proceeded despite the report of the Tinbergen Committee, that it was not required in commodity taxation [3], and with the assistance of the reports of other distinguished economists, such as the group led by Fritz Neumark in general taxation [2]. The latest of these is the important and impressive report on the integration of the capital market of the European Economic Community, prepared by a Group of Experts under the chairmanship of Professor Claudio Segré of the Commission staff.

The Group of Experts maintains that harmonization takes place in response to the pressure of problems (p. 80) and that it is inevitable (p. 243), needed not only to merge the investment resources of the separate countries in the Community but to increase their volume (p. 209). Many of the faults in the functioning of domestic capital markets, and institutional weaknesses, can be

overcome by their progressive integration (p. 256) since the faults of functioning of national security markets are the result principally of their narrowness and compartmentalization (p. 280). Integration is especially needed to provide more "transformation" (financial intermediation) which is not an end in itself but is sought as a remedy to excessive public preference for liquidity (p. 56). The fundamental disequilibrium on European markets is the chronic excess long-term demand for credit over the supply, which leads to state intervention to keep the supply reserved for home borrowers (p. 99). Such financial intermediation as does take place diverts liquid savings to government investment, mortgages, and sometimes government enterprise (p. 55), the last of which has especially large demands for credit because of its practice of holding prices low (p. 132). Wider markets will permit the development of specialized institutions for underwriting securities and maintaining secondary markets (pp. 212, 243). In particular, banks perform too many functions such as investing for their own account, distributing securities and providing security advice to customers. In this they run the risk of conflicts of interest (p. 242).

The Group of Experts is not the first to make these points. Earlier in the field have been U. S. Secretary of the Treasury Douglas Dillon, in a speech at Rome in May 1962, and the Joint Economic Committee of the Congress, for which the U.S. Treasury prepared a background report, omitting, however, any reference to the important Amsterdam market [4]. Separate national studies have been undertaken in France and Belgium. But the Segré report is by all odds the most complete, the broadest, and the most detailed, the report with the most far-reaching recommendations on a wide range of issues.¹ Its 30 tables bring together the most up-to-date and detailed statistics comparing various aspects of the capital markets of the Six, and frequently those of the United Kingdom and the United States, as well. It is, as I have said, impressive and important.

Capital-market institutions and their regulation evolved differently in different countries owing to historical differences in experience and the accident of diverging paths to protect the saver and to maintain the viability of institutions during the depression, war, and postwar recovery. There are some general trends, such as excessive public liquidity preference, the necessity for governmental financial intermediation, and the tendency of government to reserve savings for its own use. But the differences are striking. Take insurance companies, for example. Insurance companies and pension funds provide 3 per cent of net financial saving in France, 9 in Italy, 10 in Germany, 14 in Belgium (20 in the United States), 39 in the Netherlands (and 40 per cent in Britain) (Table 12). With its high liquidity preference, "which cannot be changed," France buys term insurance rather than straight life (p. 47). Life insurance companies separately furnish average annual increments in reserves per capita for the capital market of \$2.50 in Italy, \$4.70 in France, \$10.70 in Belgium, \$12.30 in Germany, and \$21.60 in the Netherlands. The respective percentages of average annual increases in reserves to gross domestic capital formation are 1.2, 1.4, 3.7, 2.9, and 4.4 (Table 27).

¹I have not seen a parallel report issued by the Organization for Economic Cooperation and Development.

With these differences in flows, there are wide differences in the latitude allowed to life insurance companies in investing their reserves in equities (p. 236) and in foreign securities (p. 335). In Luxemburg both equities and foreign securities are proscribed to life insurance companies. In the Netherlands, domestic life insurance companies are subject to no restrictions with respect to either, although foreign life insurance companies operating in the Netherlands are not allowed to invest abroad. A complex variety of rules, limits, and requirements has been laid down separately in Belgium, France, Germany, and Italy. The well-known concern of the Dutch monetary authorities that Dutch savings should serve Dutch needs on a priority basis, with some limit to foreign access to the Dutch capital market, is not ignored in the report (pp. 99, 131). The statistics on life insurance, plus the infrastructure needs of localities, furnish its explanation.

The Group of Experts believes that the Community's capital market can be integrated without the emergence of a single dominant financial center (p. 226). They adduce a long list of specific proposals for harmonization, although in some fields such as bank regulation, more study is called for before specific rules can be laid down (p. 243). They also recommend reform, such as the improvement of company accounts (annex to Chapter 11), and refer in frequent places to a new directive under preparation in the Commission to relax remaining exchange controls.

Among the most interesting recommendations is support for the proposal of Professor Pfleiderer, president of the provincial central bank of Baden-Wuerttemberg, that the spread around parities in exchange rates be eliminated to reduce exchange risks (p. 346). The suggestion is straightforward, in contrast with the irony with which Professor Harry G. Johnson put it forward several years ago [1], and makes clear that proposals for bands and flexible rates are essentially directed to international disintegration. The Experts recognize that a flat rate of exchange is a step on the way to monetary union, when all exchange risks within the Common Market, they suggest, would be eliminated (p. 340). This requires harmonization of monetary policy, which they favor (p. 326). The deeper question is not addressed, however, whether harmonization is enough so long as economic sovereignty is retained by the constituent members. Is harmonization a three-quarter-way house which cannot be occupied indefinitely? Suppose the member countries differ among themselves as to the weight to attach to such targets as full employment, price stability, or balance-of-payments surpluses (possibly for accumulating claims in the United States which can be converted into gold)? Or suppose a major structural change reduces the demand for the output of a country. If factor movements failed to produce a new equilibrium would it be condemned, like Appalachia, to seek adjustment through deflation alone, without the assistance which devaluation can provide? The Experts, of course, cannot be called upon to look beyond harmonization, which is their assignment, but a reviewer may be permitted to raise the question.

There is one other delicate issue on which the Report goes only a certain distance. Directed to the question of integration of the Six, it does not ask whether a wider integration with New York, London, or the Euro-currency

and Euro-issue markets would be more efficient. There is no discussion of the analogue in capital markets of trade-creation and trade-diversion, the extent, that is, to which the development of a European capital market limited to the Six is a second-best solution, inferior to the integration of a world capital market. There is a section on the Euro-issue market (pp. 216 ff.); it is mentioned that European countries have difficulty in maintaining independent monetary policies so long as they are connected to the Euro-issue market, but that they cannot restrict access to this market for fear of handicapping the competitive position of national companies (p. 222). The role of the American network of banks in the Community is noted (p. 163) and the spread of American firms they serve (p. 164). Reasons are given why European banks do not have similar networks, although growth and American competition may stimulate their construction. Harmonization of taxes within the Community must keep an eye cocked at tax levels in third countries or EEC capital will leave the Six for abroad (p. 202). The European investor has a clearer picture of the position of American corporations than of European because of the fuller company reports the former publish (p. 264). 195 American securities are quoted on the Amsterdam exchange as opposed to 30 issued by Holland's EEC partners; even in Brussels and Paris American securities are almost as numerous as EEC, 23 to 44 for Brussels, and 32 to 40 for Paris (Table 27).

Economic integration among the Six has already gone a considerable distance, with the help of outside factors. The Report recognizes the role of the Euro-dollar market in tending to equalize interest rates (p. 84). Parallels can be found in Mediterranean immigrants in the labor market, and American corporations in the markets for certain commodities. To the extent that the EEC frees up regulations and permits wider capital movement, will distinctions be drawn between the Six and the outside world? Is the recommendation for permitting the *caisses centrales* which invest savings banks funds on a national basis to buy foreign securities without limit, and local savings banks and *caisses* to buy them in limited amounts (p. 333) restricted to Community securities? It does not say so.

The Report of the Group of Experts is a landmark in the discussion of a vital question of current international economics. Its importance extends far beyond the Community, and it is to be hoped that in an intellectual trade-creating gesture, the Community will make it available in translation in that medium of exchange, widely used in the world, English.

Latin American Economic Integration—Experiences and Prospects. Edited by MIGUEL S. WIONCZEK. New York: Frederick A. Praeger, 1966. Pp. xiv, 310. \$7.50.

A Latin American Common Market? By SIDNEY DELL. New York and London: Oxford University Press, for Royal Institute of International Affairs, 1966. Pp. ix, 336. \$8.80.

These two books, particularly the Dell volume present useful historical and analytical background concerning economic integration in both South and Central America, though the many changes and developments that have occurred since they were written have somewhat reduced their timeliness. The Wionczek volume never really had a chance: most of its nineteen essays were originally written in 1964 (a brief essay by Tinbergen was written in 1959!), and the volume originally appeared in Mexico in a Spanish language edition. The Dell volume was written in April 1965. Recent analytical writing, notably by Harry G. Johnson, carries the debate over trade discrimination further than in either of these books.

The Wionczek volume is a collection of nineteen essays; the authors include both economists and officials. In general, it is an undistinguished volume, though several of the essays, particularly Wionczek's own contributions, are of value. Nevertheless, it is a book that warrants attention from economists interested in Latin America or in the inter-relation of trade and development. The central theme of the volume is set forth by Wionczek in his introductory essay: "The integration doctrine elevates to the multinational plane the thesis that economic development is impossible without industrialization. According to this thesis, the sustained growth of an underdeveloped economy depends on the degree to which an active process of substitution of imports by domestic production can be promoted, so as to extend the country's capacity to import to cover the acquisition of an optimum volume of capital goods and technology." This theme is familiar and has been better presented and defended elsewhere. Yet the essays in this volume convey the flavor of economic policy debates from the point of view of true believers and demonstrate how successful Raul Prebisch, Gunnar Myrdal *et al.* have been in getting their ideas bureaucratized. Economists can continue to debate the ideas themselves but, for better or worse, economic policy in Latin America and elsewhere in the underdeveloped world increasingly reflects them. For true believing free traders no good can come of this. For others, the problem is more complicated. The essays in this volume confront the reader with the variety and complexity of the issues involved in Latin American economic integration. By their inadequacy they lead the concerned reader to realize how much yet remains to be done,

theoretically as well as practically before a coherent doctrine of economic relations among less developed countries (LDC's) can be developed. Economic theory today still gives little guidance to the policy maker interested in knowing which of the many forms of economic integration is most desirable, what sorts of compensation arrangements are necessary and desirable, how much reliance should be placed on market forces and how much planning must be done, which countries should band together economically, and a host of related practical issues.

The Dell volume is somewhat more current and a good deal more ambitious intellectually. Superficially, it looks like a vigorous defense of economic integration as a means for stimulating economic growth. For example, the Preface states that "The rate at which these countries [all LDC's] are able to move towards tolerable living standards may depend to a great extent on their ability to form larger and more viable economic units." But the sense of mission is considerably diluted, and the author confronts us with a perplexed and troubling problem to which no pat answer is given. Dell stresses that regional integration is no substitute for "political, economic and social reform," and that to make integration work, joint multinational planning is necessary. "But if regional planning is unrealistic for Latin America, so also is a common market in that area unrealistic" (p. 212). Nationalism is a powerful but not a benign force: Dell finds it leading directly to protectionism and *étatisme*—both forces with which regional integration must find a *modus vivendi* if it is to be effective politically and economically.

Dell has written a thoughtful and useful book. But it stops short of a direct confrontation of the potential conflict between the economic and political requirements of economic integration and development. Economic nationalism may look to economists like a shabby trick that is being played on the peoples of the developing world, but is this really the case? Political stability is not easily come by, yet it is an important, perhaps essential, requirement for sustained economic progress. If the price of such stability is a higher degree of protection or government control than is economically optimal, it may still be worth paying. In any event, it is this potential conflict that lies at the heart of the problem of Latin American economic integration and that has still had inadequate scholarly attention. More narrowly, once economists make their peace with economic nationalism, there is much that they can do in helping to analyze its cost. Indeed, economic integration in Latin America may prove to be less significant as an engine of growth than as a means of reducing the costs of protection.

It should be noted that neither volume offers a very useful compilation of statistical or bibliographical material. The Wionczek volume has a skimpy bibliography (English language titles only), no index, and very little statistical information. The Dell volume has an index, a somewhat better bibliography, a few tables and two very useful documentary appendices containing Article XXIV of the GATT, the Montevideo Treaty, the General Treaty on Central American Economic Integration, and other material.

Washington, D.C.

Debt Servicing Capacity and Postwar Growth in International Indebtedness.

By DRAGOSLAV AVRAMOVIC, ASSISTED BY RAVI GULHATI. Baltimore: Johns Hopkins Press, 1958. Pp. xvi, 228. \$5.00.

Debt Servicing Problems of Low-Income Countries, 1956-1958. By DRAGOSLAV

AVRAMOVIC AND RAVI GULHATI. Baltimore: Johns Hopkins Press, 1960. Pp. xvii, 74. \$2.50.

Economic Growth and External Debt. By DRAGOSLAV AVRAMOVIC AND ASSO-

CIATES. Baltimore: Johns Hopkins Press, 1966 [c.1964]. Pp. xiii, 207.

\$6.00.

These three books cover the work over the past several years of Mr. Avramovic and his colleagues at the World Bank on the debt servicing problem of less developed countries. The first two are largely factual presentations showing the increase in debt servicing payments since World War II together with the growth in such relevant variables as income, savings, and export earnings. For the period 1946-1955, Avramovic concludes that debt servicing was not a serious burden on the less developed nations. These charges increased somewhat more rapidly than export earnings and income, but public debt service amounted to only 3.7 per cent of the export value of goods and services in 1955. Thus, "in general it appears that gains in production and trade . . . during the first postwar decade not only enabled the borrowing countries to maintain service on their obligations, but also provided a foundation for further productive investment."

In the second and third books listed above, which cover the period after 1955, Avramovic begins to emphasize the rapid rise of debt service charges in relation to the export earnings of the developing nations. As a recent OECD study has pointed out, the ratio of public debt to the export earnings of these countries rose steadily from 3.8 per cent in 1956 to 10.8 per cent in 1965. One result of this has been mounting pressure by the less developed countries to be granted easier terms on their borrowed capital. The last book in the group is in part a response to such pressure. It was prepared in response to requests by OECD and UNCTAD for a paper discussing the factors determining a country's debt servicing capacity. Unlike the other studies it is largely analytical.

For the typical primary producing country with limited export possibilities and yet a reasonably high growth target, Avramovic sets up seven specific conditions which have to be met for the mechanism of international lending on "hard" terms to work successfully. These are: (1) Creditors must agree to lend continuously despite high service ratios and despite the rigidities in the balance of payments of their debtors; (2) Debtors must manage their external accounts in a way which enables them to pay their bills when due; (3) Fluctuations in export earnings of the debtors must be greatly moderated; (4) The "cash squeeze" problem of countries which have to repay an extremely large proportion of their debt over the next few years must be solved; (5) The return on capital must be higher than the international rate of interest; (6) The plough-back of profits must be high enough so that at some point domestically generated savings exceed domestic investment requirements and thus leave a surplus which can be used to meet service payments; and (7) In-

vestment must be sufficient to enable total output to grow at a satisfactory rate. In a final essay Avramovic states that all of these conditions could be reduced to one, namely: a high level of investment that yields a high rate of return.

There is no doubt about the difficulty of specifying in any simple way the determinants of such an elusive concept as a country's debt servicing capacity, and Avramovic and his colleagues approach the problem from several different viewpoints. For example, J. P. Hayes in a very interesting essay explores the matter by using a growth model of the Harrod-Domar type. Assuming some constant growth rate, a given initial and marginal domestic saving rate, and a fixed capital-output ratio, he analyzes the growth of external debt in relation to the interest charges on this debt. A "critical" interest rate is defined as that rate at which the external debt will increase at the same rate as gross domestic product. Interest rates higher than this are considered to result in a problem of unmanageable indebtedness in the long-run. The author concludes from this analysis that there are in fact a number of less developed countries with fairly low saving rates and high capital output rates that are unlikely to be able to sustain more than low per capita growth rates unless interest levels on their indebtedness averages substantially less than 5-6 per cent.

One problem in using simple growth models with fixed capital-output and marginal-saving ratios for analyzing a subject such as this is that they tend to divert attention from variables over which governments may have considerable control and which may be very important in determining a country's transfer ability. Although Hayes specifically points out the limitations of these models, there is a tendency throughout the book to assume that the less developed countries themselves have very little room for policy manipulation. There is, for example, no discussion of what types of exchange rate policies, fiscal policies, or monetary policies may help or hinder a country's effort to meet its transfer burden. There is emphasis upon the importance of using foreign funds in a productive manner, but even a rapid rate of growth is no guarantee that a government can meet its debt obligations. Fiscal, monetary, and exchange rate measures must be followed that produce an export surplus from the situation of rapid growth, and this is by no means a simple and easy goal to achieve. Probably Avramovic and his associates felt that these policy considerations were too well known to be worth very much discussion. However, their generally very balanced and sensible analysis of the problem might usefully have been broadened by more attention to appropriate policy measures that could be taken by the less developed countries themselves.

ROBERT E. BALDWIN

University of Wisconsin

International Financial Aid. By WOLFGANG G. FRIEDMANN, GEORGE KALMANOFF, AND ROBERT F. MEAGHER. New York and London: Columbia University Press, 1966. Pp. xiv, 498. \$13.75.

The major part of this book consists of four long chapters. The first reviews the methods and policies of the principal aid-giving countries, the second surveys the experiences of a number of aid-receiving countries, the third examines

several aid-supported projects and programs, and the last is concerned with general policy issues. These four big chapters are sandwiched between two shorter ones, on the magnitude of aid and the future of aid.

Much of the most useful material is on the individual projects and programs. The discussion of loans to Colombia and Chile (written by Raymond Mikesell) is especially instructive. These pages document in revealing fashion the great difficulties involved in negotiating, implementing, and administering foreign loans. Even where all participants are in general agreement and eager to get on with the job, delays seem almost inevitable, and actual costs invariably exceed estimates by a substantial margin. No new theories or generalizations emerge from this material, but what does come through clearly is that the mere mechanics of public lending are as troublesome as are the more frequently discussed theoretical aspects.

The other chapters are considerably less helpful. The first long chapter on the institutions and policies of donor countries is largely descriptive of rather pedestrian matters. There is a great deal of information on names of aid agencies, size of loans and grants in recent years, paid in capital, and so on, but the reader is unlikely to gain much understanding or insight into the logic or rationale of aid giving. Where some explanation is attempted, the result often sounds like a government handout. The German emphasis on loans, for example is said to be "due to the conviction that charity is neither desirable nor in the interest of developing countries, since it would tend to inflate demand and shield the recipients from the hard realities of economic life" (p. 75).

The chapter on aid-receiving countries covers nine individual countries and one region (East Africa) in 100 pages. Since there is no central hypothesis or model to guide us, the result is necessarily a rather cursory view of the problems these countries have in obtaining and using foreign aid in their development efforts. The chapter on policy matters includes comments on a wide range of issues: repayment arrangements, tied aid, project vs. general development aid, bilateral vs. multilateral, etc. There are isolated points in this chapter of interest, but the chapter does not build from the preceding descriptive materials nor do the authors bring out in a very clear fashion the essential nature of the problems. For example, the tying of aid by the United States (and other countries) is attributed to balance of payments problems, but no mention is made of how or why aid aggravates these problems. The reader unacquainted with world liquidity problems, reserve currencies, and all that, will not be satisfied (or enlightened) with the assertion that aid is tied to help protect the balance of payments. Or, the reader who might have learned that the productivity of capital in capital poor, labor rich economies is high may wonder why repayment of a foreign loan is such a problem. Such a reader will learn from this book that it is a problem, but he will not learn why.

Instructors of development courses may find the chapter on projects and programs (Ch. 5) useful as collateral reading for their students. They (and others) however must look elsewhere for a searching review of the economics of foreign aid.

Business Finance; Investment and Security Markets; Insurance

Optimal Financing Decisions. By ALEXANDER A. ROBICHEK AND STEWART C. MYERS. Englewood Cliffs: Prentice Hall, 1965. Pp. x, 166. \$2.50.

The recent growth of specialization and knowledge in the field of financial management has given rise to numerous "satellite" books. These books are designed to examine a particular subject in depth and are used in conjunction with a more general text. *Optimal Financing Decisions* is such a satellite book. Its stated purpose is to "present a systematic application of financing theory to the problem of the firm's financing decisions."

The authors take a normative approach to problem solving. They attempt to "erect a theory of how rational investors *should* value stocks." When armed with this theoretical framework, the financial manager will be aided in the decisions that confront him.

For analytical purposes, the book is divided into two parts. The first two-thirds of the book develops a theory of stock value by examining each of the major factors affecting this value, namely, income, leverage, dividends, growth, and uncertainty. The final third of the book then brings together all these factors to form a basic valuation formula and to study problems of short- and long-term financing.

Thus, it is necessary to understand the methods by which the basic valuation formula was derived. First, three methods of measuring income are examined; the accounting method, the internal rate of return method, and the discounted present value method. Of these three, the discounted present value method was selected as being most appropriate.

Next, the general problem of leverage yields interesting, though at times confusing, presentations of the Modigliani-Miller hypothesis and the "traditional" point of view. Modigliani-Miller argue that given certain constraints, the value of a firm is independent of the relationship of debt to equity. According to the traditional viewpoint "stockholders' value per share can be increased by judicious use of debt." If, however, the leverage becomes too high, the value per share will decline. After twenty-nine pages of exhaustive argument, it is ironic to find that both positions lead to a similar conclusion, that there is some degree of leverage which will maximize the value of the firm. Unfortunately, there is no agreement as to exactly what combination of debt and equity will satisfy that condition.

The discussion of debt and equity is followed by an enlightening discourse on dividend policies and the reinvestment of earnings. Building on the earlier concepts, the authors conclude that the value of a share of stock is the discounted present value of its expected dividends. This, then, leads into the issue of growth, which centers largely around the works of M. J. Gordon. Gordon assumed that the dividend payout ratio and the rates of return of future investment were constant. He also found these factors to be highly significant in explaining variations in stock prices. It is argued, therefore, that investors put great weight on past historical trends, such as the dividend record, in ascertaining the risk and value of a company's stock.

The final factor affecting stock value is uncertainty. In this connection, a detailed study is presented of risk aversion, utility, and the use of "certainty equivalents" which reflect the attitudes of individuals toward risk.

In the final third of the book, all of the previously mentioned factors are brought together in a basic valuation formula. Essentially this formula consists of the discounted present value of expected dividends and is not an equation to be solved, but one that is intended to be used by financial managers as a guide in formulating policy.

Finally, the book turns from the abstract world of model building to the more mundane problems of the real world. Problems of short-term and long-term financing are examined in light of the basic valuation formula. Furthermore, the authors effectively demonstrate the use of simulation techniques, linear programming, and the Monte Carlo method as systematic approaches to problem solving.

In conclusion, the book represents a valuable addition to financial literature. It brings together in a cogent and useful manner numerous hitherto unrelated theories. Furthermore, it offers the reader an opportunity to see the application of quantitative tools in making financial decision. Finally, its in-depth analysis of conflicting theories and techniques will act as an invaluable guide to the serious student of finance.

BENTON E. GUP

Industrial Organization; Government and Business; Industry Studies

Performing Arts—The Economic Dilemma. By WILLIAM J. BAUMOL AND WILLIAM G. BOWEN. New York: Twentieth Century Fund, 1966. Pp. xvi, 582. \$7.50.

Because of this book's subject matter, it will interest many readers who take no notice of most volumes reviewed in this journal. Baumol and Bowen are excellent ambassadors for the economics profession. Their study may convince skeptical humanists that economic research can illuminate the conditions of the arts and also that some leading economists can write readable prose. The book is an important contribution to public discussion of the quality of consumption, as distinguished from its quantity. Readers will be rewarded not only with insights and information about large issues but also with factual tidbits with which to enliven their dinner table conversations.

The study presents an impressive amount of information about live professional performances of orchestral music, chamber music, opera, ballet, modern dance, and the theater. It includes data on costs and revenues of performing groups and the characteristics of their audiences, mainly in the United States but with ample comparative data on Great Britain. Much of the material is from primary sources, and its collection was complicated by the large number of organizations and the informality and incompleteness of records. The authors refer to "months of searching through dusty files in cramped backstage

offices, hundreds of hours spent collecting questionnaires from audiences in every part of the country and every type of performance, many interviews with producers, managers and choreographers, and a massive correspondence." The statistics are skillfully used in a text that should not be too abstruse for general readers, to whom the book is primarily addressed. Extensive appendices (about 125 pages) give additional details and information on methods.

In deflating over-enthusiastic reports about the "cultural boom," Baumol and Bowen note that most of these fail to allow for population growth, the declining value of money, and rising income and consumption levels. From 1929 to 1963 real per capita expenditures on arts admissions hardly changed; in relation to disposable income they declined about one fourth, from 0.15 per cent of disposable income to 0.11 per cent.

The audience for the performing arts is found to be drawn from "an extremely narrow segment of the American population." Its members are well educated, have high incomes, are predominantly in the professions, and are mainly in their youth or early middle age. Sample surveys indicate that in 1963-64 more than half of men and almost one-third of women in the audience had done graduate study (compared with 5 per cent of men and 2 per cent of women in the whole urban population). The median income of the performing arts audience was twice that of the urban population. Differences among audiences for the several art forms are minor. British audiences are similar to American in economic and social composition.

A principal thesis of the study is that the arts suffer from cost pressures similar to those experienced by many other service industries. Although performers' earnings are often low, their compensation tends to rise over time along with the general wage level. But in the arts, unlike other industries, opportunities for technological progress are narrow, and rising wages are not offset by increased productivity.
